# CEOS Biomass Protocol Executive Summary

- Biomass maps are vital for understanding and mitigating climate change
- New biomass products are being produced from satellite missions
- Differences between products may lead to confusion and reduced uptake
- There is a need for clear guidance on generating and using these products
- The CEOS biomass protocol is aimed at both users and producers of biomass products

## **Biomass maps are important for understanding and mitigating climate change**

Forest biomass, defined as the dry-weight of the standing live or dead woody component of aboveground vegetation, has been recognized as a Global Climate Observing System (GCOS) Essential Climate Variable (ECV), a critical input to the United Nations' (UN) Reducing Emissions from Deforestation and Degradation-plus (REDD+) program, and an important input to Earth system models. Spatially continuous maps of forest biomass are therefore important inputs for decreasing the uncertainties in the global carbon cycle, underpinning forest management and climate mitigation strategies, and global carbon cycle science.

## **New satellite biomass products are being produced**

To address the need to estimate biomass globally, several recent and upcoming Earth Observing (EO) missions will collect satellite data giving information on forest structure and aboveground biomass. We anticipate these datasets will drive development of many new global forest biomass products. Some of these products will be official mission products, but many will be generated independently by scientists, Non-Governmental Organizations (NGOs) and other interested parties, each potentially adopting a different combination of mission data, training data, and statistical algorithms according to needs and resources.

## **Multiple new products may lead to confusion and reduced uptake**

New biomass products will not necessarily agree with each other, and will vary in quality, spatial resolution and date of prediction. Products that disagree with each other will likely cause confusion and without consistent validation users will not know which products to trust.

## **There is a need for clear guidance**

This protocol will assist biomass map producers in good practices for estimating and reporting uncertainties in their products, and will inform users how to interpret products and conduct independent validation. The goal of this protocol is to facilitate consistent and transparent biomass product uncertainty estimation so that products can be used effectively for science, forest management and policy applications.

## **Anticipated protocol audience**

This protocol is aimed at three primary audiences: 1) Biomass map product producers aiming to improve and standardize how uncertainties are reported for increased product utility, 2) Biomass map product users needing to understand how reported uncertainties are estimated, and 3) Those wishing to perform independent validation of biomass products, either with new or existing reference data.

## **Summary of Protocol Content and Recommendations**

- **Common agreed-upon definitions**
- **The requirement for more high quality reference data**
- **Uncertainty propagation from field measurements and biomass models to maps**
- **Independent validation: necessary but proceed with caution**
- **Recommendations for compilation of new reference datasets**

## **Definition of biomass**

We define biomass as the dry mass of live or dead matter from tree or shrub (woody plant) life forms, typically expressed as a per area density (e.g. Mg of aboveground biomass per hectare). Thus, we do not include non-woody or belowground biomass. When discussing individual tree or plot total biomass (not density), the definition is Aboveground Biomass (AGB), whereas for plot or pixel level densities, as commonly estimated in mapped products, the definition is Aboveground Biomass Density, usually per hectare (AGBD/ha).

## **High quality reference data are required**

High quality biomass reference data are required both to produce accurate biomass maps, and to conduct product validation. This point may seem obvious, but the most direct high quality biomass reference data, weighed tree biomass, are very difficult to acquire for anything other than small numbers of trees. Instead, we rely on easy-to-make tree size measurements (e.g. stem diameter, total tree height) and the use of statistical (allometric) models to translate these size measurements into estimates of biomass. Many errors and uncertainties are included in reference data, and many existing biomass measurements from field plots have such high uncertainties that they are inappropriate for generating or validating products.

This protocol makes specific recommendations for establishing reference measurements in forests, including the use of traditional measurements and both terrestrial and airborne lidar.

## **Airborne lidar biomass maps are key tools for scaling between field plots and satellite products**

Airborne lidar is now operationally acquired throughout the world. These data can be used with local field plots to create reference maps at multiple spatial resolutions so that a single site can be used to validate the full suite of anticipated satellite biomass products, regardless of their spatial resolution. This protocol presents recommendations for the acquisition of airborne lidar (sensors, sampling designs, etc.) as well as guidance for linking field plots to airborne lidar data, fitting local biomass models, and propagating and reporting uncertainties in reference maps. There are also recommendations for how to subsequently link airborne lidar maps to satellite products.

## **Propagating uncertainties from field measurements and biomass models to maps**

Existing biomass products often (but not always) estimate uncertainties from the statistical models used to link field biomass estimates to satellite remote sensing data. These uncertainties are typically underestimated when they do not include measurement, geolocation and allometric modeling uncertainty (i.e. calibration uncertainty). This protocol provides recommendations on how best to estimate and reduce errors, as well as how to propagate these to estimate uncertainties of biomass products at a range of scales.

## **Independent validation is necessary but should be conducted with caution**

Using existing field plot biomass estimates to validate biomass products is important, but it can introduce so much uncertainty that the results may become meaningless for many applications. This is particularly true for small plots in heterogeneous forests, plots with high geolocation uncertainty, plots with a temporal lag between field and satellite data collection, or plots where individual tree information is not available. It is recommended to filter reference data to a minimum quality standard prior to conducting independent validation.

## **Recommendations for compiling new reference data**

New reference data are required to update existing reference measurements (either to make them current, or improve them to meet the standards recommended in the protocol). There are many geographic domains with insufficient reference data, or where uncertainties in biomass products cannot be accurately estimated due to a lack of data. It is recommended that new datasets are routinely collected, in collaboration with existing networks, that both update and

gap-fill existing reference datasets. These recommendations are summarized in Table 0.1 (also in Tables 8.1, 8.2).

**Table 0.1 Recommendations for collection of biomass reference measurements**

<p><b>Recommendations for all data collections</b></p> <ul style="list-style-type: none"> <li>• Data should be free and open access within at most 1 year after data collection</li> <li>• Data should be acquired in collaboration with long term field plot networks and local partners wherever possible</li> </ul>	
<p><b>Field Plot Recommendations</b></p> <ul style="list-style-type: none"> <li>• Square plots <ul style="list-style-type: none"> <li>◦ Easier to link to gridded products</li> </ul> </li> <li>• Large plots (minimum 0.25 ha in tropics, ideally 1 ha plots with 25 or 50 m subplots) <ul style="list-style-type: none"> <li>◦ Minimizes edge effects and geolocation uncertainties</li> </ul> </li> <li>• Smaller plots (&lt;0.25 ha) are acceptable outside of tropics provided airborne lidar available</li> <li>• Stem-mapped where possible</li> <li>• Geolocated with high accuracy, and reported uncertainties</li> <li>• Trained botanist should be employed for species identification</li> </ul>	<p><b>Airborne Lidar Recommendations</b></p> <ul style="list-style-type: none"> <li>• Minimum 4 shots /m<sup>2</sup>, ideally ≥ 8 shots/m<sup>2</sup></li> <li>• Preferably acquired same season as field plots</li> <li>• Acquired within 2 years, ideally 1, of field data acquisition</li> <li>• Repeated every ~5 years or when disturbance is detected</li> <li>• Wall-to-wall coverage of at least 10 km<sup>2</sup> <ul style="list-style-type: none"> <li>◦ Cover both the plots and local environmental and forest structure gradient</li> <li>◦ Smaller area of coverage acceptable if only UAV-LS lidar available</li> </ul> </li> </ul>
<p><b>Spatial Distribution of Field Plots</b></p> <ul style="list-style-type: none"> <li>• Plots cover environmental gradients under airborne lidar collection that are locally or regionally correlated to biomass (e.g. topographic gradients)</li> <li>• Sufficient number of plots collected to train a lidar model (min approximately 30, depending on complexity of system)</li> </ul>	<p><b>Terrestrial Lidar Recommendations</b></p> <ul style="list-style-type: none"> <li>• Data collection in new or existing long-term plots <ul style="list-style-type: none"> <li>◦ Data augments field measurements, does not replace them</li> </ul> </li> <li>• 1 ha plots preferable</li> <li>• Data acquired in a grid pattern</li> <li>• Spacing 10 m in dense forests, 20 m in open areas <ul style="list-style-type: none"> <li>◦ Can be changed to ensure consistent sampling and minimize occlusion</li> </ul> </li> <li>• Instrument must have ability to range tallest trees in 1 ha plots (150 m range)</li> <li>• Repeated ~ every 5 years or when disturbance is detected</li> <li>• Multiple scans need to be coregistered (either through use of targets or with sensor that has automatic coregistration)</li> </ul>

## Summary of Good Practice Recommendations and Current Data and Knowledge Gaps

Each chapter in the protocol is summarized in terms of good practice recommendations and community highlighted knowledge and data gaps. These gaps include both gaps in data acquisitions (as particularly highlighted in Chapter 8) but also areas where further research or tool development would help progress biomass validation activities. Table 0.2 provides a summary of these recommendations. Note that a more detailed summary of these recommendations is found in Chapter 7, and for complete details the reader should refer to the source chapter.

**Table 0.2 Summary of protocol recommendations by chapter**

Chapter	Good practice recommendations	Knowledge and/or Data Gaps
<b>Collection of Reference Data (Chapter 2)</b>	<ul style="list-style-type: none"> <li>• Collect data following recommendations in Table 0.1</li> <li>• Report measurement and model uncertainty for plot-level AGBD estimation</li> </ul>	<ul style="list-style-type: none"> <li>• Standardization across field measurement protocols for AGBD estimation</li> <li>• Tool development for automated TLS and UAV-LS processing</li> <li>• More research on how to estimate wood density in the field</li> <li>• Improvement of generalized allometric models using larger samples and TLS</li> </ul>
<b>Linking field, airborne and satellite data (Chapter 3)</b>	<ul style="list-style-type: none"> <li>• Collect large, well geolocated, preferably square plots (see Table 0.1)</li> <li>• Develop local AGBD maps using high quality wall-to-wall airborne lidar data and locally trained AGBD models</li> <li>• Maps should be at the spatial resolution of plots or subplots and can be subsequently aggregated</li> <li>• Estimate and report per-pixel uncertainties in lidar AGBD maps to aid validation</li> </ul>	<ul style="list-style-type: none"> <li>• A quality control framework for systematic airborne lidar AGBD maps following protocol recommendations</li> <li>• Further research into spatial propagation of uncertainty for per pixel estimation</li> <li>• Tools to facilitate lidar AGBD map production and comparison with satellite biomass maps</li> </ul>
<b>Error estimation and propagation (Chapter 4)</b>	<ul style="list-style-type: none"> <li>• Error reporting should comply with IPCC good practices guidelines</li> <li>• Measurement and modeling errors should be estimated following appropriate inference method and propagated to mapped products</li> </ul>	<ul style="list-style-type: none"> <li>• Online tools to facilitate error estimation and propagation for product producers and independent validation</li> <li>• Extension of existing tools (e.g. BIOMASS package) outside of tropics and from field plots to mapped products</li> </ul>
<b>Making products and validation useful for different communities (Chapter 5)</b>	<ul style="list-style-type: none"> <li>• Uncertainties should be clearly and consistently reported</li> <li>• Adoption of consistent terminology and methods to error and uncertainty estimation by all map producers</li> </ul>	<ul style="list-style-type: none"> <li>• Biomass product harmonization or intercomparison activities would facilitate uptake</li> <li>• Annually updated harmonized estimates would aid policy uptake</li> <li>• Definitions of forest/non-forest by community require consensus for product intercomparison and change analysis</li> </ul>
<b>User-led Validation (Chapter 6)</b>	<ul style="list-style-type: none"> <li>• Only conduct independent validation with user provided data if data are appropriate for validation (contemporaneous, complete metadata, same resolution as satellite products)</li> <li>• Conduct thorough data screening and filtering prior to conducting validation</li> </ul>	<ul style="list-style-type: none"> <li>• Simple online tools to facilitate data screening, filtering and error estimation</li> </ul>
<b>Protocol Implementation (Chapter 8)</b>	<ul style="list-style-type: none"> <li>• Work with existing plot networks to collect and curate reference data</li> <li>• Follow measurement recommendations in Table 0.1</li> <li>• Independent validation should be transparent, consistent and repeatable</li> <li>• Collection of new contemporaneous field and airborne lidar datasets over a set of globally representative Biomass Reference Measurement Sites (BRMs).</li> <li>• Reference data should be made free and open</li> </ul>	<ul style="list-style-type: none"> <li>• New and updated BRMs data collection, particularly in existing geographic gaps (continental asia, drylands, dense tropical forests)</li> <li>• Independent validation should be conducted on an open access platform with publicly available user-friendly tools (e.g. on MAAP platform or similar)</li> </ul>

### Suggestions for Using Protocol by Different Groups

Of the three audiences anticipated for this protocol (biomass product generators, biomass product users, and those wishing to collect biomass reference data), the following flow charts may facilitate reading of the protocol. Naturally, many readers will occupy multiple categories, but the following flow charts were designed to guide specific readers to the chapters we deem most relevant for each of these three audiences.

Fig 0.1 Flowchart for using the protocol to aid in generation of biomass products and uncertainty reporting.

**Fig 0.2** Flowchart for using the protocol to aid biomass product users in either interpretation or independent validation of biomass products.

**Fig 0.3** Flowchart for using the protocol to aid in the consistent collection of high-quality forest reference biomass measurements.

# Chapter 1: Introduction

Forest biomass has been recognized as a Global Climate Observing System (GCOS) Essential Climate Variable (ECV), a critical input to the United Nations' (UN) Reducing Emissions from Deforestation and Degradation-plus (REDD+) program, and an important input to Earth system models (Herold et al., 2019). Spatially continuous maps of forest biomass are therefore an important input for reducing uncertainties in global carbon stock and flux estimates from forests, particularly for areas where insufficient ground or airborne lidar data are available. Accurate biomass products are of great importance for forest management and climate mitigation. However, due to a previous dearth of satellite data specifically designed for producing accurate estimates of forest structure (Goetz et al., 2009), few global-scale forest biomass products are currently available, and the assessment of their accuracy is challenged by a lack of appropriate reference data. To overcome this critical carbon accounting gap, several upcoming Earth Observing (EO) missions will collect satellite data sensitive to forest structure and aboveground biomass, defined as the dry-weight of the live or dead woody component of aboveground vegetation. We anticipate a multitude of new global forest biomass products in the coming decade, but foresee challenges in their intercomparison and validation across biomass products. These challenges have already been highlighted by several studies comparing the few existing continental or global-scale biomass products (Avitabile et al., 2016; Avitabile & Camia, 2018; Baccini et al., 2012; Huang et al., 2015; Mitchard et al., 2013; Saatchi, Harris, et al., 2011; Santoro et al., 2015; Thurner et al., 2014), and may hinder the effective adoption of biomass products for various policy, management and science applications.

A specific example of the importance of independent biomass product validation comes from comparisons of two widely known pantropical biomass maps (Baccini et al., 2012; Saatchi, Harris, et al., 2011). By independent, we mean using reference data that were not included in the generation of products, and ideally conducted by a third party. Despite having been produced from the same core satellite datasets (the Geoscience Laser Altimeter System [GLAS] and the Moderate-resolution Imaging Spectroradiometer [MODIS]), these maps differ substantially in several tropical areas (Avitabile et al., 2016; Mitchard et al., 2013, 2014) potentially because they employed different empirical modeling approaches, calibration datasets, and extrapolation techniques. However, the exact causes of discrepancies between these products, or indeed a determination of the more accurate product for a given application, is not possible without common approaches to independent validation. Aboveground biomass product validation is challenging, primarily because of the paucity of high-quality, publicly available, and globally representative reference sites with well-characterized uncertainties, and challenges related to the fact that these reference data are not direct measurements but rather estimates based on tree-level allometric model predictions (D. B. Clark & Kellner, 2012). Indeed, in the pantropical case, the map producers themselves had limited available validation datasets, and Baccini et al. (2012) and Saatchi et al. (2011) performed cross-validation of their map products using a subset of GLAS data that were deliberately left out of their biomass model training, rather than validating with an independent dataset. While Saatchi et al. (2011) conducted an error propagation for the final estimated uncertainties associated with their pantropical product, and

Baccini et al. (2012) reported confidence intervals on their estimates per continent, the degree of accuracy of these products in geographic areas outside the calibration range, or at the various resolutions needed for policy implementation (Herold et al., 2019), was not possible. These products have been compared to the Intergovernmental Panel on Climate Change (IPCC) Tier 1 biomass estimates, following the 2006 IPCC Good Practice Guidance (GPG; IPCC, 2003, 2006). Although a composite of the two pantropical products was suitable to replace IPCC Tier 1 estimates when national inventories were not available, it was recommended that national estimates be favoured over these remote sensing-based estimates, given the large disparities between the products and national inventories (Langner et al., 2014).

This is not a criticism of past biomass products. Indeed, historic biomass products are a function of the data (ground through to satellite) available at that time. Global products are typically produced at a grid cell size relating to the spatial resolution of the global image data source utilized. Larger pixels can be expected to obscure local variability and result in lower variance outcomes. Comparison to higher resolution data, such as from samples of lidar data, illustrate these issues (e.g. Bolton et al., 2013). As the spatial resolution of global image data options have gotten finer, so too has the detail and quality of large area biomass products. The next generation of biomass products from new mission datasets are expected to improve upon these past examples, and the sheer number of missions will result in a larger number of products to compare and validate. Indeed, the issue of product validation will become even more pressing as the number of spaceborne datasets specifically designed to map ecosystem structure increases (e.g., the National Aeronautics and Space Agency's (NASA's) Global Ecosystem Dynamics Investigation (GEDI), the NASA/Indian Space Research Organization's (ISRO's) NASA-ISRO Synthetic Aperture Radar (NISAR), the European Space Agency's (ESA's) BIOMASS, and the Japanese Aerospace Exploration Agency's (JAXA's) Advanced Land Observing Satellite (ALOS)-4), and approaches to biomass estimation using these data diversify. Previous biomass products have varied in terms of the spatial and temporal resolution, modeling approach, geographic scope of calibration data, scaling, error propagation, and uncertainty reporting (Goetz et al., 2009; Huang et al., 2015; Mitchard et al., 2013). To effectively meet the goals of scientists and decision makers, the global change community requires well-tested validation approaches that are transparent and flexible (with respect to geographic scope and spatial resolution).

The Committee on Earth Observation Satellites (CEOS) is an international body that works to coordinate Earth Observation programs and data collected by space agencies. For nearly two decades, the CEOS Working Group on Calibration and Validation (WGCV) has had a sub-group specifically focused on Land Product Validation (LPV). In close coordination with CEOS member agencies, the LPV subgroup has recognized the need for good practices and protocols to guide biomass product validation in advance of the expected suite of upcoming biomass products. This LPV subgroup launched the biomass focus area in 2017 to help gather community support in developing a validation protocol for the products that will be generated from the upcoming biomass-related missions.

## 1.1 Earth Observation Missions for Biomass Mapping

NASA's Ice Cloud and land Elevation Satellite (ICESat) was launched in 2003, and its Geoscience Laser Altimeter System (GLAS) instrument collected global waveform lidar measurements over vegetation that were used to estimate forest height and structure until the last ICESat laser failed in 2009 (Abshire et al., 2005). GLAS data were not designed to study forest structure, but these data have nevertheless become popular for biomass mapping. These data are relatively sparse in spatial sampling, and each lidar footprint illuminated a nominally 65 m diameter circle, which resulted in the mixing of reflected signal from ground and canopy surfaces, ultimately presenting challenges for estimating biomass in areas of high relief or structural complexity (Duncanson et al., 2010). Despite these challenges, many wide area biomass maps used GLAS data to map forest structure (e.g. Baccini et al., 2008; Margolis et al., 2015a; Saatchi, Harris, et al., 2011; Simard et al., 2011; Su et al., 2016).

Several current and upcoming missions (e.g. GEDI, BIOMASS, NISAR) should provide improved data for biomass mapping compared to those earlier sensors as they are designed with a primary science goal of mapping forest biomass. Official mission biomass products are expected from each of these missions, but because of the publicly available nature of these mission datasets we also expect a host of other new biomass products through data fusion and alternative algorithms, etc. We therefore anticipate the release of products with a range of spatial resolutions, geographic extents, and temporal domains. Table 1.1 shows the expected resolution of core biomass products from upcoming spaceborne missions themselves, but fusion products will likely present both coarser and higher resolution maps.

Many of these missions have specific biomass product accuracy requirements as part of the criteria by which mission success is determined (Table 1.1). Independent validation of these products at their nominal resolution would help demonstrate that requirements have been met. This is particularly useful if validation of biomass products from each mission or estimation approach can be conducted at the same set of sites, allowing direct comparisons between accuracies of each product in different forest types, environments, disturbance histories, etc. Comparisons between official mission products and other new biomass maps will also allow the community to appreciate the accuracy impacts of algorithmic improvements, data fusion approaches, etc. on product accuracy and ultimately reduce confusion and latency in the adoption of new biomass mapping approaches.

**Table 1.1 Current and expected biomass-relevant missions.** Note that only NISAR, GEDI and BIOMASS are approved missions with a formal requirement for biomass mapping accuracy. Missions with no official biomass product are marked Not Applicable (NA), and missions that have yet to publish requirements are to be determined (TBD).

Mission	Funding Agency	Launch Date (Expected)	Data Type	Measurement resolution	Biomass map Resolution	Geographic Domain	Accuracy Requirement
ICESat-2	NASA	09/2018	532 nm photon counting lidar	13m footprint aggregated to 100-m transect	NA	Global	NA
SAOCOM 1A	CONAE	10/2018	L band SAR	10-100m depending on mode	NA	Global	NA
GEDI	NASA	12/2018	1064 nm waveform lidar	25 m circular footprint	1 km <sup>2</sup>	ISS (+/- ~51.6°)	<20% standard error for 80% of forested 1 km cells
SAOCOM 1B	CONAE	08/2020	L band SAR	10-100m depending on mode	NA	Global	NA
ALOS-4	JAXA	(2022)	L-band SAR	1-25 m depending on mode	NA	Global	NA
NISAR	NASA/ISRO	(2023)	L-band SAR	3 - 10 m (depends on mode)	1 ha	Global	<20% RMSE for <100 Mg/ha
BIOMASS	ESA	(2022)	P-band SAR	60 x 50 m with >6 looks	4 ha	Global except western Europe and North America	<20% RMSE for AGB >50 Mg/ha; 10 Mg/ha for AGB ≤50 Mg/ha
MOLI	JAXA	(2023)	1064 nm waveform lidar	25 m circular footprint	NA	ISS (+/- ~51.6°)	NA
TanDEM-L	DLR	(2023)	L-band SAR	TBD	1 ha	Global	20% accuracy or 20 Mg/ha
Copernicus HPCM ROSE-L	ESA/EC	(2027)	L-band SAR	TBD	1 ha	Global	TBD

## 1.2 CEOS Validation Stages

**Table 1.2 CEOS validation stage hierarchy.** The eventual goal is to mature existing and forthcoming biomass products from stage 0 to 4.

Validation Stage - Definition and Current State		Variable
0	No validation. Product accuracy has not been assessed. Product considered beta.	
1	Product accuracy is assessed from a small (typically < 30) set of locations and time periods by comparison with in-situ or other suitable reference data.	<b>Snow</b> <b>Fire Radiative Power</b> <b>Biomass</b>
2	Product accuracy is estimated over a significant (typically > 30) set of locations and time periods by comparison with reference in situ or other suitable reference data.  Spatial and temporal consistency of the product, and its consistency with similar products, has been evaluated over globally representative locations and time periods.  Results are published in the peer-reviewed literature.	<b>fAPAR</b> <b>Phenology</b> <b>Burned Area</b> <b>Land Cover</b> <b>LAI</b>

3	<p>Uncertainties in the product and its associated structure are well quantified over a significant (typically &gt; 30) set of locations and time periods representing global conditions by comparison with reference in situ or other suitable reference data. Validation procedures follow community-agreed-upon good practices.</p> <p>Spatial and temporal consistency of the product, and its consistency with similar products, has been evaluated over globally representative locations and time periods. Results are published in the peer-reviewed literature.</p>	<p><b>Vegetation Indices</b></p> <p><b>Albedo</b></p> <p><b>Soil Moisture</b></p> <p><b>LST &amp; Emissivity</b></p> <p><b>Active Fire</b></p>
4	<p>Validation results for stage 3 are systematically updated when new product versions are released or as the interannual time series expands.</p> <p>When appropriate for the product, uncertainties in the product are quantified using fiducial reference measurements over a global network of sites and time periods (if available).</p>	

## 1.3 Definitions

This chapter provides definitions used in this protocol and relevant to global aboveground biomass map training and validation.

### 1.3.1 Definition of Aboveground Biomass

For the purposes of CEOS LPV the definition of aboveground biomass density is the above ground standing dry mass of live or dead matter from tree or shrub (woody plant) life forms, typically expressed as a mass at the individual tree level, or a mass per unit area (density) for mapped products. The most common unit of reporting is in Megagrams, or tonnes, per hectare, Mg/ha.

There is no single universally accepted definition of aboveground biomass across different user communities. Other definitions of aboveground biomass include: considering live wood only; including leaf mass; including woody and/or non-woody debris. The definition we use here is most relevant for earth observation: measurements respond to standing biomass only; optical observations, particularly lidar, are sensitive to living and dead standing biomass; radar observations are sensitive to mostly living woody biomass due to moisture content and the size of scattering objects relative to wavelength. We note also that allometric models that are used to translate EO measurements to aboveground biomass do not universally or systematically consider the fraction of live and dead wood in their calibration data.

### 1.3.2 Definition of Biomass Allometric Model

Aboveground biomass has been measured for several thousand trees globally, and related to tree dimensions (i.e. stem diameter, tree height and sometimes crown area) and wood density of those trees using regression techniques to produce so-called "allometric models". These models are used to estimate aboveground biomass from the dimensions and the species of individual trees recorded in forest inventory plots.

### **1.3.3 Definitions of Associated Physical Parameters**

#### **Stem volume**

Stem volume is the volume of the whole stem of an individual tree, measured in cubic meters.

#### **Growing stock volume**

Total volume of the stems of all living trees per unit area ( $\text{m}^3/\text{ha}$ )

#### **Wood density**

The density of a wood sample is its oven-dry mass divided by its fresh volume, given in units of  $\text{g}/\text{cm}^3$ . Wood density is the conversion factor used to translate between volume to biomass. Wood density is a key functional trait in plants, and a common explanatory variable for many allometric models. The wood densities of many tree species are held in a global database, allowing wood density to be estimated from taxonomic information collected during forest inventories.

#### **Stem diameter**

Stem diameter is a structural measure of the girth of an individual tree. Diameter is typically measured 1.3 m above the ground, known as diameter at breast height (DBH), or 50 cm above buttresses, stilt root, or deformities, if present. Stem diameter, along with tree height and wood density, can be used to predict aboveground biomass using allometric relationships.

#### **Tree height**

Tree height is a structural measure of the vertical distance between the ground level and the tip of an individual tree. Tree height is often used in allometric models to estimate biomass, and is either measured in the field or estimated from trunk diameter through locally-calibrated or generic models rather than measured.

#### **Canopy height**

Canopy height is the vertical distance between the ground level and the highest point of tree tops, measured from any given location in a forest.

#### **Canopy cover**

Canopy cover is the proportion of ground area which overlaps with forest canopy in a vertical profile of a given local area.

#### **Tree density**

Tree density is the number of trees in a given area divided by that area, reported as stems/ha.

### **1.3.4 Definitions of Spatial and Geometrical Aspects**

#### **Coregistration**

Coregistration is the recording of the spatial location of multiple samples to allow them to be paired. Coregistration is necessary for matching ground-based and remotely sensed measurements, and for pairing multiple adjacent or overlapping remote sensing measurements.

#### **Incidence angle**

The incidence angle is the angle between a ray approaching the surface and nadir. The incidence angle can play a large role in mismatch between remote sensing measurements and ground measurements.

#### **Occlusion**

Occlusion is the obstruction of distant objects by near objects from the perspective of a laser scanner.

#### **Point density**

Point density ( $\text{m}^{-2}$ ) is the number of lidar pulses reflected and recorded per unit area by a laser scanner. The point density is determined by the frequency of the scanner, the velocity of the scanner motion, and the amount of overlap between coregistered samples.

#### **Point cloud**

A point cloud is a three-dimensional representation of forest structure via discrete measurements of surfaces. Point clouds can be generated through laser scanning or stereoscopic structure from motion images. Structural measurements such as stem diameter, tree height, and stem volume can be derived from point clouds.

#### **Region of interest**

An area ( $\text{m}^2$ ) containing reference data.

#### **Canopy Height Model (CHM)**

Airborne lidar data are often used to produce high resolution canopy height maps. These maps can be used to correct plot geolocation error, check the accuracy of field measured heights, and as an input to local airborne lidar aboveground biomass density (AGBD) maps.

### **1.3.5 Definitions of Other Key Terms**

#### **Forest**

The standard Food and Agriculture Organization (FAO) definition of forest is areas outside urban and agricultural land uses that are treed, with trees taller than 5 m and having 10% tree cover or more (FAO, 2018). This definition results in large areas of dry and semi-arid tropics that are not tree-dominated being classed as forest, and current debate about the global extent of forests in

dryland areas (as derived from high resolution optical imagery) hinges on details of definition (Bastin et al., 2017; Griffith et al., 2017). For the purposes of this overview we adopt as simple an operational definition of forests as possible, as ‘land with largely continuous tree cover’.

### **Reference data**

In this document, reference data are biomass estimates used during calibration and validation of remotely sensed biomass products, which are measured independently from the biomass products being assessed, and are not included in product training data. Reference data are ideally high-quality field measurements and/or airborne maps, following a standardised measurement protocol and traceable uncertainty estimates, at the same spatial resolution as the remotely sensed data source, and sampled across the full range of locations, site characteristics and the dynamic range that are present in the biomass product.

### **Calibration**

Calibration in remote sensing is the process of assessing and correcting for systematic error in remotely sensed datasets, while for the purposes of this protocol it is used to mean model training and development, and/or assessing and correcting for systematic error in biomass products through comparison with reference data.

### **Validation**

Validation is the process of determining the quality of measurements and biomass model outputs through comparison with reference data.

## **1.3.6 Definitions of Validation Metrics**

The validation process quantifies the following metrics in a statistically rigorous way over multiple locations and time periods representing global conditions. The definitions of these validation metrics have been sourced from the “Evaluation of measurement data: Guide to the expression of uncertainty in measurement” (GUM-2008) published by the Joint Committee for Guides in Metrology (JCGM, 2008).

### **Bias**

Bias is the difference between this estimator's expected value and the true value of the parameter being estimated. Bias in an estimator or procedure may produce systematic error in the results (in this case the biomass map).

### **Error**

Error of measurement is the “result of a measurement minus a true value of the measurand” (JCGM, 2008, p. 36). The true value is not known, but typically “a number of results of measurements of a quantity is used to establish a conventional true value” (JCGM, 2008, p. 33). In the case of biomass measurements, which may depend on multiple “values of quantities other than the measurand, the errors of the measured values of these quantities contribute to the error of the result of the measurement” (JCGM, 2008, p. 37).

Error is composed of systematic error (bias) and random error. Systematic error is the “mean that would result from an infinite number of measurements of the same measurand carried out under repeatability conditions minus a true value of the measurand” (JCGM, 2008, p. 37). Random error is the “result of a measurement minus the mean that would result from an infinite number of measurements of the same measurand carried out under repeatability conditions” (JCGM, 2008, p. 37).

### **Uncertainty**

Uncertainty is the distribution of errors for an estimate. Components of uncertainty include systematic error (bias) and random error (precision). Uncertainty may arise from a range of measurement and model errors, and both systematic error and precision should be accounted for in uncertainty estimation and reporting.

### **Accuracy**

Accuracy of measurement is the “closeness of the agreement between the result of a measurement and a true value of the measurand” (JCGM, 2008, p. 35). Measurements are more accurate when they have smaller error values.

### **Precision**

Precision is the repeatability and reproducibility of the results of measurement. Repeatability is the “closeness of the agreement between the results of successive measurements of the same measurand carried out under the same conditions of measurement” (JCGM, 2008, p. 35). Reproducibility is the “closeness of the agreement between the results of measurements of the same measurand carried out under changed conditions of measurement”(JCGM, 2008, p. 35).

# Chapter 2: Generation of Reference Datasets

This chapter provides an overview of errors and uncertainties in field reference datasets as well as recommendations for how to minimize these errors given the current state of knowledge. Section 2.1 focuses on forest measurements in the field (e.g. physical measurements of trees), Section 2.2 focuses on uncertainties in allometric models, which estimate field biomass from measured attributes. Section 2.3 focuses on good practices for using newer technologies (Terrestrial Laser Scanning (TLS) and to a lesser degree unmanned airborne vehicle (UAV) lidar) to augment more traditional measurements and reduce uncertainties. This chapter provides guidance on good practices for ground estimates of forest biomass, and can be used in combination with field measurement protocols from plot networks as a guide for those seeking to establish new plots for biomass reference, or for those seeking to interpret existing plot data.

## 2.1 Field Measurement Errors

Keryn Paul, Nicolas Barbier, Grant Domke, Laura Duncanson, Tommaso Jucker, James Kellner, Oliver Phillips, and Jerome Chave

### 2.1.1 Background

Ideally, remotely sensed data should be related to biomass measurements obtained by harvesting and weighing all woody vegetation within an area of interest to minimise measurement errors in ground-based biomass reference data (D. B. Clark & Kellner, 2012). However, such extensive harvesting is rarely possible nor desirable, due to insufficient resources and/or due to protection laws associated with the study site. Hence, operationally, we estimate rather than measure biomass of woody vegetation using inventory studies. Given results from inventory studies are only estimates of biomass, they encompass some degree of measurement error and modeling error (D. B. Clark & Kellner, 2012). This Chapter focuses on measurement errors in the generation of biomass reference data.

There has been much interest in identifying key sources of error in stand biomass estimates (e.g. Berger et al., 2014; Chave et al., 2004; Magalhães & Seifert, 2015b; Molto et al., 2013; Shettles et al., 2015), including for calibrations of emerging technologies in remote and terrestrial sensors (e.g. Kalliovirta et al., 2005). However, many error propagation analyses have either excluded measurement errors, or made broad assumptions regarding their magnitude (e.g. Gertner & Dzialowy, 1984; Magalhães & Seifert, 2015b).

This Chapter considers field measurement errors when applying either allometric models or terrestrial remote sensing (e.g. TLS or UAV) to provide plot- or transect-based estimates of biomass stored as woody vegetation. Plot selection or placement within a study site, and the size, shape, and geolocation are considered key sources of measurement error, however they are not considered here given this topic is comprehensively discussed in Section 3.1; *‘Geolocation and spatial scale’*. The application of particular models or protocols for allometric- or TLS/UAV-based estimates of biomass also induce measurement errors, but these are considered in Sections 2.2

and 2.3; ‘Allometric error’ and ‘TLS and UAVs’. Here we consider three other key areas of potential measurement error when applying either allometric models or TLS/UAV to provide plot- or transect-based estimates of biomass carbon of woody vegetation, and provide recommendations for minimizing uncertainties in plot estimates of AGBD. We touch briefly on a) plot geolocation and extent which is discussed in greater detail in Section 3.1, and provide a discussion of uncertainties associated with b) incomplete inventories, c) tree attribution (i.e. health, species), and d) destructive harvesting of trees for inclusion in allometric models.

Note that specific recommendations for measurements (e.g. tree height, diameter, species) are often ecosystem dependent, and thus there is no single recommended protocol for field measurements in the validation of global biomass products. However, we outline the sources of uncertainty in field biomass estimation in general, and make general recommendations for reducing these uncertainties. For specific measurement recommendations we refer practitioners to Table 2.1, and recommend that measurements are collected following the protocol of the plot network for the ecosystem in question.

## 2.1.2 Incomplete Biomass Inventories

Plot-level biomass estimates often have errors associated with incomplete inventory of individual trees within a plot. These are both by design (e.g. not sampling trees smaller than a given diameter) or accidental (e.g. through uncertainty of plot boundaries leading to undersampling of trees at a plot's edge). These inadvertent and intentional incomplete inventories are discussed below.

### 2.1.2.1 Inadvertently incomplete inventories

#### *Sources of error*

Even if plot boundaries are accurate, inventories of individuals within the plot may be incomplete due to operators inadvertently excluding certain sources of biomass. For example during the inventory assessments, new recruits such as re-sprouting trees or shrubs may be missed, or some larger trees may be inadvertently missed (e.g. O. L. Phillips et al., 2002). This will result in under-estimates of plot-level biomass. Similarly, if plot boundaries are inaccurate, 'edge effect' errors in AGBD estimates may be incurred through inconsistencies in the inclusion of individuals along the plot boundaries. Plot boundaries may be inadvertently over- or under-estimated such that individuals along the boundary may be incorrectly included or excluded from the sample which, in turn, results in over- or under-estimates of plot-level biomass.

#### *Examples of quantification of measurement errors*

To our knowledge, there are no previous studies that provide quantification of the error attributable to operators inadvertently either: (i) missing accounting for trees or new recruits such as re-sprouting trees or shrubs when undertaking plot inventories, or; (ii) incorrectly marking plot borders during inventories of stand biomass assessments, thereby assigning individuals measured within these plots to a plot area that is incorrect. In challenging terrains and/or dense vegetation that impede an operators 'line-of-sight', accurate placement of measurement tape or pegs indicating plot boundaries may be compromised. These conditions make it difficult to ensure each individual within the plot is accounted for during the inventory, and also make it difficult to ensure accurate plot layouts.

### *Recommendations for validation*

In stands of relatively high stocking densities, **it is recommended** that operators minimise the risk of inadvertently missing individuals within the plot by visually marking (e.g. by tape or spray paint) each individual once it has been accounted for. This will make it easier for operators to check that *all* individuals within the plot were actually measured as expected. Under steep or complex topography, bearings and tape measurements will not coincide. If the reference area considered has to be horizontal (i.e. perpendicular to the local zenith), then the bearings have to be trusted when selecting which individuals to include in the inventory.

To minimise edge-induced measurement error, particularly in such challenging environments, **it is recommended** that small plots be avoided as these have relatively large perimeter-to-area ratios. Forest Observation System values of aboveground biomass (AGB) and canopy height estimates with their associated uncertainties are provided at a 0.25 ha scale from field measurements made in permanent research plots across the world's forests. For permanent sample plots with multiple re-measurements, edge-induced measurement error may also be minimised through clearly marking plot boundaries using permanent corner posts or metal stakes for plot and/or subplot boundaries. In the case where single measurement inventory plots are desired (which would not follow our primary recommendations but may be used to train local biomass maps or as part of a forest inventory program not primarily focused on biomass), edge-induced measurement error can be minimised through the use of circular plots or transects (i.e. long narrow plot, e.g. 100 m long by 5 m wide). In circular plots, once the central point is located, a tape measure of set length may be extended along the radius to a point along the perimeter to confirm whether or not an individual is included within the circular plot. Similarly in transects, once the starting point has been located, a tape measure of set length (e.g. 100 m) may be placed on the ground along a set bearing. Then, the operator may confirm whether or not an individual is included in the transect by using a stick of set length (e.g. 2.5 m) to extend either left or right from the tape, thereby clearly indicating the boundary.

#### **2.1.2.2 Deliberate incomplete inventories**

##### *Sources of error*

A second related source of error in stand-level biomass may be attributable to inconsistencies in the deliberate exclusion of certain sources of biomass. For example, it is relatively common in many biomass assessment studies that stems below a lower size class limit be deliberately excluded on the basis that they are laborious to measure and contribute relatively little to total stand-level biomass (e.g. D. B. Clark & Kellner, 2012). Similarly, relatively inaccessible species such as woody climbing plants (e.g. lianas or vines) are often deliberately excluded from inventories, thereby further contributing to under-estimates of biomass in some forest types (e.g. Chave et al., 2004; O. L. Phillips et al., 2002). Some forest inventory assessments of stand biomass also

deliberately exclude understorey species (K. D. Johnson et al., 2017) and any individuals that are assessed as being predominantly dead (Chao et al., 2009).

#### *Examples of quantification of measurement errors*

Small individuals: Small trees (<10 cm diameter) tend to not be included in inventories for stand biomass assessments given the common assumption they contribute relatively little to total biomass. However, Schroeder et al. (1997) showed that their contribution depends on the successional stage. They found that in stands of <50 Mg/ha, biomass with trees of <10 cm DBH contributed ~75% of the biomass of trees >10 cm DBH, whereas the proportion dropped to 10% for stands with aboveground biomass >175 Mg/ha. Thus, for most temperate hardwood forests, ignoring the small diameter trees may significantly underestimate total carbon storage in live biomass.

Woody climbing species: Although lianas are commonly excluded from inventories, these have been shown to represent up to 5% of total biomass in some tropical forests (Hegarty & Caballé, 1991), and are expected to increase their proportional contribution under a changing climate and increased disturbance regimes (O. L. Phillips et al., 2002). Additionally, given their relatively higher leaf:mass ratio, liana signals will have a disproportionate impact on satellite remote sensing signals compared to trees.

Understorey species: Recent work by Johnson et al. (2017) indicated that in various forest types across the United States (US), the exclusion of understorey species would result in an underestimate of total biomass, with understorey species comprising approximately 2% of the total aboveground live tree carbon pool.

Dead individuals: Clearly, as for small, climbing and understorey individuals, the errors in stand biomass estimates that result from exclusion of dead individuals in the inventory will depend on their relative contribution to the population of the total stand. In mature tropical forests necromass can form a large fraction of total aboveground biomass. For example, in Amazonia the mean ratio of necromass to aboveground biomass is 0.127, implying that mature Amazonian forests store a total necromass of  $9.6 \pm 1.0$  Pg C (Chao et al., 2009). But this varies substantially, with this study showing necromass is twice as great in forests with low stem mortality rates than in forests with high stem mortality rates ( $58.5 \pm 10.6$  and  $27.3 \pm 3.2$  Mg ha<sup>-1</sup>, respectively). The impact of excluding dead individuals is therefore substantial, and variable, and typically exceeds the impact of excluding understorey trees or lianas.

#### *Recommendations for validation*

**It is recommended** that inventories of AGB be complete, with all components of AGB being measured, even if resource limitations necessitate that components be measured with a precision that reflects their relative likely contribution to total stand biomass. For permanent biomass reference plots, in particular, measurements of small trees, standing dead trees, and commonly ignored species such (e.g. lianas, palms) should be measured. For example, for small trees (<10 cm diameter) or dead trees, **it is recommended** that they be included in the inventory,

albeit with their stem diameters measured using highly efficient instruments such as the Stepped Diameter Gauge (Paul, Larmour, et al., 2017). **It is also recommended** that inventories include woody climbing species using standardised protocols (e.g. O. L. Phillips et al., 2002). For non-permanent plots measured to train airborne datasets, where logistics for taking these additional measurements are challenging, estimates of the relative contribution of AGB from these other pools should be made (e.g. from smaller plots as in the US Forest Inventory and Analysis (FIA) program).

In summary, to minimize uncertainties regarding incomplete inventories, **we recommend**:

- Large plots ( $\geq 1$  ha)
- Visually tagging trees that have been measured (e.g. with tape)
- Measurement of all trees that contribute to biomass (including small trees, lianas, palms, etc.), using subplots to estimate relative contributions where logistics prevent measurement of every individual.
- Measurement and recording the status of standing dead trees

### **2.1.3 Attribution of individuals within the plot**

#### *Sources of error*

Individual trees are typically attributed with a botanical identification (species, family, plant functional type (PFT)), and as live or dead. All individuals within selected plots are generally assessed for these key attributes, as these are considered to have an important influence on their biomass. Different species or groups of species have differing structure and stem woody density, and hence, differing biomass. Another common attribute considered is a subjective assessment of the health of the individual (e.g. dead, or partially dead, etc.) given the extent of dead woody material or hollows that an individual contains will influence its average stem wood density. This is particularly important in stands with high rates of mortality. If the attribution of such characteristics is inconsistent between operators or studies, errors will result from incorrect assignment of allometric models or estimates of stem wood density.

In tropical forests, identifying trees is a challenge that integrated assessments of biomass have to address. This is because tree species composition regulates how much carbon forests store (Baker et al., 2004). The biomass contained in trees is governed by the volume and density of their wood, and while the former can be sensed remotely by satellite, the latter in general either cannot, or is estimated indirectly as a function of species / PFT (Ustin & Gamon, 2010). The density of tree wood is mostly determined by a tree's genetic identity, and so (except in rare occasions where wood density may be directly measured for every single tree) we need to identify the tree. This is ideally done to species, and certainly at least to genus with which most variation in wood density is associated (Baker et al., 2004). This challenge is greatest in tropical forests where there are often thousands of tree species and several hundred tree genera present

locally. Even a single hectare of forest in Amazonia can have up to 300 tree species, some potentially unknown to science (Gentry, 1988).

### *Examples of quantification of measurement errors in tree attribution*

Errors or inconsistencies in attribution between operators or studies may result in biased estimates of stand biomass. However, this is discussed only briefly here given that errors or inconsistencies in attribution of species within plots manifests through to possible biases via the application of inappropriate models using either allometrics or TLS/UAV based estimates of biomass, which is discussed in detail in Chapters 2.2 and 2.3, respectively.

As an example, in studies where allometric models based on PFT are applied (e.g. Paul et al., 2016), an incorrect attribution of a tree to a category of PFT will result in a 16-37% error in the individual's aboveground biomass, depending on the tree size. Incorrect attribution of a shrub or small multi-stemmed tree to another plant functional type will result in a 24-36% error in the individual's aboveground biomass, depending on its size (K. I. Paul, personal communication, 2019). Similarly, based on generic allometric models, incorrect attribution of a eucalypt tree or acacia shrub to a 'live' rather than 'dead' condition will result in errors of up to 36-39%, depending on the size of the individual (K. I. Paul, personal communication, 2019). Clearly, given the magnitude of these possible errors at the individual-level, errors at the stand-level will depend on: (i) how many individuals are inaccurately attributed, and; (ii) whether there is bias resulting from consistent incorrect attribution, e.g. of 'dead' individuals being attributed as 'live', etc.

With respect to tree species identification, identity can impact forest biomass via volumetric allometric differences and especially due to wood density. Species composition varies at all spatial scales, thus bias and uncertainty result if individual identity is ignored. A recent pan-tropical review found that compositional differences cause variation in forest biomass and carbon density of up to 20% locally, and that additional large-scale floristic variation leads to variation in tropical forest mean wood density of up to 30% (O. L. Phillips et al., 2019). Across the lowland tropics basal area-weighted wood density values range widely, from 0.467 to 0.728 g cm<sup>-3</sup> at the regional scale (and is more variable still for individual forest plots). Consequently, tropical biomass assessment requires locally validated measurement of tree-by-tree botanical identity.

### *Recommendations for validation*

To minimise errors resulting from inaccurate or inconsistent attribution of individuals within the inventory sample, **it is recommended** that; (i) standard protocols be made available to provide clear definitions of the different categories for guiding attribution to available allometric models or TLS/UAVs; (ii) these standard protocols include clear instructions on how to attribute

individuals as either 'live' or 'dead', and; (iii) operators be well trained and experienced in identification of individual trees and shrubs.

Efforts to map and monitor tropical forest carbon using remote sensing techniques should be combined with tree-level measurement of species identity by botanists working in inventory plots. This requires integrating botanical expertise and associated costs into the core processes of biomass assessment.

**It is also recommended** that the biomass community ensure that they work with trained botanists dedicated to making and curating herbaria collections (vouchers), and do not rely simply on the allocation of names in the field. This is because plant identification requires collection of material, making herbarium vouchers from these, identifying these in herbaria, and storing them permanently. Thus, with vouchers we have scientific reproducibility, and names become hypotheses which can be tested over time. Without vouchers, names are opinions, and their quality cannot be evaluated.

**Further, it is recommended** that biomass reference plots be permanent samples, not one-off forest inventories. This is because tropical trees are sterile most of the time and the lack of flowers or fruits degrades identification quality. Given the often short and unpredictable phenologies of many tropical trees, forest inventories miss the reproductive period of most species (Baker et al., 2017). Permanent plots that can be repeatedly collected provide greater long-term potential for reliable identifications, and so minimise uncertainty in wood density.

**It is recommended** to upload digital copies of collections to digital herbaria archives that are integrated with forest plot databases. This is because accurately assessing spatial variation in species (and hence wood density) and tracking long-term biodiversity change is challenging to do consistently for large numbers of plots. We also need to standardise the process of identification across time and space, requiring the ability to make side-by-side comparison of multiple voucher specimens digitally. High-resolution specimen images are increasingly available online: for example ForestPlots.net (Lopez-Gonzalez et al., 2011) is implementing workflows and software to allow on-screen comparison of multiple high-resolution plot voucher specimens and images of living plants.

We note that the benefits of working with established permanent plots goes beyond simply improving confidence in identifications. There are other benefits including being able to match individual trees from TLS surveys (Section 2.3) to tagged and censused individual trees (See Section 2.3), e.g. via post-hoc matching from the registered point cloud. Integration with repeatedly measured biomass reference 'super-site' plots where long-term botanical and ecological inventory is supported will provide the highest quality and greatest certainty to the biomass community (Chave et al., 2019).

In summary, to minimize errors in tree species identification and health attribution **it is recommended** that:

- Plots are collected following existing measurement protocols in an appropriate forest plot network for the ecosystem in question (e.g. ForestGeo, Forestplots, Afrifron)

- New plots be integrated into an existing plot network
- Standard protocols are adopted for classification of trees as live vs. dead, again following existing measurement protocols in an appropriate forest plot network for the ecosystem in question (e.g. ForestGeo, ForestPlots.net, Afritron)
- Forest reference measurements are collected by individuals trained for attribution of trees as live/dead
- Well-trained botanists familiar with the regional flora are involved in plot collection
- Plots become permanent plots, integrated into an existing plot network and setup with the intention of long-term measurement
- Digital copies of plot data are uploaded to digital herbaria archives that are then integrated with established forest plot databases.

### 2.1.4 Measurement of stem diameter

Stem diameter ( $D$ ) is one of the most easily measured variables commonly applied in allometric models predicting biomass or wood volume (e.g. Berger et al., 2014). There is variation between studies in the tools used for  $D$  measurement and the height of the stem at which these measurements are made. Tools used for  $D$  measurement include stem diameter tape, callipers, Biltmore stick, laser callipers sector-fork, terrestrial laser scanner, laser-camera, laser-relascope, and Stepped Diameter Gauges (SDG). Regardless of the tool used, for commercial tree species,  $D$  is traditionally measured at a height of 130 cm above the ground (diameter at breast height, DBH, or  $D_{130}$ ). This is ergonomic and avoids lower positions where the stem is often non-circular (Biging & Wensel, 1988; Gregoire et al., 1990). But for many shrubs and young or multi-stemmed trees,  $D$  measurement is impractical at this height, with measurements generally taken below the most common point at which the stem divides into multiple leaders (West, 2009), typically at 50, 30 or 10 cm above the ground;  $D_{50}$ ,  $D_{30}$  or  $D_{10}$ . Another important protocol for  $D$  measurement entails the handling of multi-stemmed individuals, which is often ecosystem dependent. In many dry and temperate forest and woodland regions, all measurements of multi-stemmed individuals ( $D_i$ ) are converted to a single value (equivalent stem diameter,  $D_e = \sqrt{\sum D_i^2}$ , cm), such that the total basal area ( $\text{cm}^2$ ) for all stems is equal to the basal area of a tree with this equivalent single diameter. In other cases, each stem is considered as an individual, and ladders are used to measure  $D$  above the split. In other cases, again, the tree is treated as a single stem if the split occurs above 130 cm, or multiple stems if the split occurs below 130 cm. The selection of the method for determining whether a split tree is considered as one or two individual stems has large implications for biomass estimation. **It is recommended to follow** a consistent protocol with the appropriate field plot network for the ecosystem in question (see Table 2.1).

#### *Sources of error*

As for all measurement variables applied in allometric models, bias in  $D$  measurements can scale-up to bias in stand-scale estimates of biomass or volume (Methley, 2001). For example, a bias in  $D_{130}$  of 5% will cause the volume per hectare to be biased by 15% (Gertner, 1990). Increasing

the sampling intensities will not decrease bias. The only means for reducing the bias is through the reduction of the bias in the actual D measurements.

Bias may result when operators are untrained (e.g. consistent incorrect placement of the tool above or below the specified height of D measurement), and when different tools are used to measure D. As discussed below, when selecting tools to measure D, trade-offs need to be considered between the time (and therefore resources) required to use them and the potential for some bias, particularly where this facilitates a greater accuracy of stand biomass estimates as more individuals can be measured (i.e. decreased sampling error) for the same level of resourcing (Paul, Larmour, et al., 2017).

Although random errors may cancel out at the stand scale, there will nonetheless always be some imprecision of D-derived stand biomass estimates due to random errors in these D measurements. Random errors in D measurement may result from a combination of recording errors (either in reading the tool or documenting results), divergences in tool placement from the plane perpendicular to the individual's axis, placement of the tool above or below the specified height (e.g. often required in complex systems to avoid stem defects or branching), and if using the tape, differences in tape tension (e.g. often required for rough- or loose-barked trees) (e.g. Elzinga et al., 2005), or measuring in close proximity to irregularly shaped stems (e.g. Weaver et al., 2015). The extent of these errors is influenced by five main factors that influence the extent of bias and precision of D measurement: (i) operator, particularly with respect to their level of training; (ii) height of the stem at which D measurement are made; (iii) form of the individual, e.g. single- or multi-stemmed individuals; (iv) size of the individual, and; (v) tool used (Paul, Larmour, et al., 2017).

#### *Examples of quantification of measurement errors*

Clearly an untrained operator may propagate bias if they consistently fail to correctly apply protocols. One common example has been the tendency for some operators to measure trees at a standard height regardless of any stem deformity, thereby causing positive bias in estimated basal area and biomass (O. L. Phillips et al., 2002). If protocols for D measurement of buttress trees are not followed to measure D above buttress, then this will result in an overestimation of biomass via allometric model application (D. A. Clark, 2002; O. L. Phillips et al., 2002).

Among trained operators no bias has been found in D measurement errors (Kitahara et al., 2009, 2010; Paul, Larmour, et al., 2017). Here the main source of bias in D measurements relates to the tool used. Numerous studies have demonstrated that differences in D measurements between alternative tools (e.g. diameter tap, Biltmore stick, calliper and SDG) increases with tree size (Moran & Williams, 2002; Wilson et al., 2007), and when measuring D of individuals with single-stems when compared to multi-stemmed individuals (Paul, Larmour, et al., 2017). Nonetheless, differences in D measurement between tools were generally negligible; averaging <0.17 cm (Behre, 1926; Gregoire et al., 1990; Kalliovirta et al., 2005; Paul, Larmour, et al., 2017; Vastaranta et al., 2008; Weaver et al., 2015).

Although not well quantified, another source of bias may result from measurement of changes in D over time within permanent sample plots. Both positive and negative biases are possible, but effects are likely to be small on AGB. For example, small bias may result from rounding up negative values in measured changes in stem diameters, and where nails were used to mark locations for D measurement, localized swelling of trees around nails may result in erroneous results (O. L. Phillips et al., 2002). Another issue with measuring changes in D is buttress creep, with bole irregularities moving up with time which requires movement of point of measurement (POM) higher up the stem (O. L. Phillips et al., 2002).

In contrast to bias, random errors in D measurement have been shown to be relatively large, with a mean standard deviation (SD) averaging  $<[1]$  cm, and a coefficient of variation (CV) of D measurements generally in the order of 2–8% (Auclair, 1986; Barker et al., 2002; Berger et al., 2014; Elzinga et al., 2005; Holdaway et al., 2014; McRoberts et al., 1994; Myers, 1961; Nester, 1981; Omule, 1980; Paul, Larmour, et al., 2017). The frequency and magnitude of these random errors are relatively consistent between the trained operators, with negligible differences in repeatability regardless of whether the repeat measures were made by different operators or multiple measurements from the same operator (Auclair, 1986; Paul, Larmour, et al., 2017). However, this may not be the case when untrained operators are employed. Larger SD (up to 2.6 cm) and CVs (up to 12.8%) have been observed when repeatability of D measurement was assessed amongst untrained operators (Kitahara et al., 2009, 2010).

When employing trained operators, the magnitude of random errors in D measurement will be predominantly influenced by: (i) height at which D was measured; (ii) size of the individual, (iii) form of the individual; and; (iv) tool used. These are discussed in turn below.

When estimating plot level biomass and associated uncertainties, statistical tools can be used to propagate measurement errors. For example, the BIOMASS package in R accounts for two types of measurement errors of D - small, frequent random errors and large, infrequent errors (e.g. due to misplacing the decimal place when transcribing values). Thus **it is highly recommended** to report these types of errors in field surveys.

Height of the stem: Recent work (Paul, Larmour, et al., 2017) has shown that for large individuals (i.e. those having  $D > 10$  cm), random errors are generally higher (often significantly) at D10, D30, or D50 when compared to D130. In contrast, for small individuals, random errors were generally the highest at D130 when compared to D10, D30, or D50. These findings may be attributed to large individuals having more random errors at lower heights due to an increase in the occurrence of irregular stem shapes at these relatively low stem heights (e.g. Weaver et al., 2015), while for small individuals, random errors at lower heights may be relatively small due to a smaller number of stems at these lower stem heights (see below).

Size of the individual: Although the standard deviation (SD) in D measurements increases with the size of the individual (Holdaway et al., 2014; McRoberts et al., 1994; Omule, 1980), when random errors are expressed in relative terms (CV), the influence of the size of the individual

becomes less important. Indeed, Paul et al. (2017) found that large individuals (i.e. those having  $D > 10$  cm) had slightly lower CV (1.9–4.9%) of D measurement when compared to smaller individuals (3.1–7.1%).

Form of the individual: Due to the possible accumulation of errors from multiple measurements, total random errors will be higher when measuring multi-stemmed individuals (and then calculating  $D_e$ ) when compared to single-stemmed individuals. Paul et al. (2017) found that the mean CV of D measurement was 1.0 to 1.2% higher for multi-stemmed individuals when compared to single-stemmed individuals. It is likely that when compared to single-stemmed individuals, when measuring D of multi-stemmed individuals, operators have greater challenges accessing the stems to measure, resulting in a greater frequency of operators failing to judge the target height of D measurement, account for differences in tape tension, or place the instrument in its proper plane.

Tool used: Although previous comparison of tools has focused on bias rather than precision, the study of Paul et al. (2017) did compare the precision of D measurement between diameter tape and the SGD; a tool having, on the end of a measurement handle, a metal plate with stepped increments of 1 cm with gaps designed to slip over stems of varying D sizes from 2 to 16 cm. They found that regardless of the form of the individual, when measuring D of small individuals, random errors were generally larger when using the SGD compared to tape. By comparison, for large-multi-stemmed individuals, outlier measurements amongst repeat measurements (leading to particularly large SDs relative to the equivalent CV) were most common when measured with tape. It is possible that use of the SDG can avoid erroneous readings as it can be quickly and easily rotated around stems of irregular shape to ensure the operator is satisfied that the reading recorded is not affected by loose bark, stem defects, or other variations. Indeed, 75% of the observations exceeding the 95% confidence interval of SDs for large-single-stemmed individuals (i.e.  $SD > 1.57$  cm) were estimated from measurements made with tape.

### *Recommendations for validation*

To minimise bias, it is paramount that operators be well trained in D measurements. This will be particularly important for operators measuring stands with numerous buttressed trees (D. A. Clark, 2002; O. L. Phillips et al., 2002). In addition, it will also be important to ensure that the tools selected are appropriate for the level of accuracy required at the individual and stand scales. In permanent sample plots where detection of small changes in D is required, accuracy of D measurements should be maximised by avoiding tools which may introduce a small amount of bias, e.g. SGD (Paul, Larmour, et al., 2017).

To minimise random errors, D measurements of large individuals ( $D > 10$  cm) should be made at a height of 130 cm (D130) (or above, when the stem is buttressed), particularly when the species is single-stemmed. For such large, single-stemmed individuals, the tool used has little influence, although use of the SDG may minimise the frequency of reading errors. For smaller individuals that are either single or multi-stemmed, random errors may be minimised by using the tape at

measurement heights <130 cm (e.g. D10, D30 or D50), but noting that additional care is required in irregular-shaped large single-stemmed individuals.

In summary, to minimize errors associated with stem diameter measurement **it is recommended:**

- Training practitioners to follow protocols in determining appropriate height to measure stems (e.g. above buttress, for multi-stems)
- For small or irregular stems, using stepped diameter gauge (SDG) instruments
- For large (>10 cm) and/or regular stems, diameter tapes, calipers and other diameter measurement tools are all appropriate.

### **2.1.5 Measurement of tree height**

#### *Sources of error*

Tree height (H; the vertical distance between the ground level and the tip of the tree) is a primary variable used in the estimation of tree and stand volume, and hence biomass. It is therefore an important variable in many inventories. However, H measurements are usually one of the more time-intensive, and therefore expensive, components of forest inventory, especially in tropical forests where tall, closed canopies, and dense understory occur, limiting the sight of tree tops.

The most direct method for measuring H (up to 25 m) involves the use of height poles. But due to the practical difficulties in measuring H directly, indirect methods are often used, generally what is referred to as the “tangent method”, which involves clinometer measurement of angles to the tree base and treetop, and the horizontal distance to the tree stem. Hand-held laser rangefinders (with electronic measurement of distances and angles) are increasingly being used to estimate H. However, rangefinders are difficult or impossible to implement in closed stands where the treetops are not easily visible.

The emergence of airborne and terrestrial lidar provides individual tree height measurements that are highly corrected with field-derived measurements (Andersen et al., 2006). These, and other alternatives such as application of stereo photogrammetry (St-Onge et al., 2004) are providing efficient alternatives to traditional field-based H measurement techniques.

#### *Examples of quantification of measurement errors*

Measuring H (up to 25 m) directly using height poles is reliable but susceptible to parallax error that can range as high as 10% (Schreuder et al., 1993). Larjavaara and Muller-Landau (2013) quantified systematic and random errors of the tangent method and laser rangefinder method as applied by five technicians to 74 trees between 5.7 and 39.2 m tall in a Neotropical moist forest in Panama. They found that the tangent method produced unbiased H estimates whereas the laser rangefinder resulted in systematic underestimates of 20% on average. However the reverse was true for random error. Random error was high using the tangent method, with overestimates of H >100% being found in about 2% of the H measurements made. The laser rangefinder method

was faster to learn, displayed less variation in heights among technicians, and so had lower random error. Others have reported that laser rangefinders can yield H measurement errors of only 1%-2% (Wing et al., 2004). But regardless of whether the tangent method or laser rangefinder method is used, the precision of field H measurements will be impacted by including the offset between measured distance and crown-top position, tree-top occlusion, ground slope, obstacles for distance measurements, and clinometer operator error (Hunter et al., 2013).

Underestimation of H has been found with airborne laser scanning (ALS), TLS and photogrammetry techniques, although in variable amounts according to local and instrument conditions (Laurin et al., 2019; St-Onge et al., 2004; Wang et al., 2019). This is because compared to field measurements of H described above, these remotely-sensed measurements of H are less sensitive to stand complexity, crown classes, and species, with occlusion effects leading to omissions of trees in intermediate and suppressed crown classes (e.g. with ALS), and incomplete crowns of tall trees (e.g. with TLS) (Wang et al., 2019). Hence, Wang et al. (2019) concluded that: (i) ALS-based H was most accurate for tall trees, and least accurate for trees in intermediate crown class, due to the difficulty of identifying treetops, and (ii) TLS-based H was reliable for trees lower than 15–20 m in height, depending on the complexity of forest stands. Laurin et al. (2019) found photogrammetry techniques resulted in lower estimates of H when compared to ALS and TLS, and that ALS and TLS gave similar estimates of H. Errors in the ALS-derived H measurement could be up to  $\pm 0.5$  m (Leckie et al., 2003), or as low of 0.02-0.3 m (Andersen et al., 2006; Reutebuch et al., 2003), with high-density, narrow beam lidar being significantly more accurate (both in terms of bias and precision) than wide-beam lidar (Andersen et al., 2006). Simultaneous use of different methods may help minimise the uncertainty in H (Laurin et al., 2019). For example, using a combination of lidar and photogrammetry, St-Onge et al. (2004) found biases averaged 0.59 m, but with bias correction using a calibration subset, this was decreased to 0.02 m.

### *Recommendations for validation*

The emergence of airborne lidar as a forest measurement tool has dramatically increased the efficiency of forest inventories. Although they may not always yield errors as low as field methods, lidar-derived H measurements reduce the cost and increase the efficiency of the inventory, thereby increasing overall accuracy at the stand-scale. **It is also recommended** that species-specific correction factors be applied to lidar-derived H measurements to maximise the accuracy of measurement (Andersen et al., 2006). The best method for producing unbiased measurements for H consists of first assessing the bias on a calibration subset of trees and then correcting all other measurements according (St-Onge et al., 2004).

In summary, to reduce uncertainties associated with tree height measurements **it is recommended:**

- Collection of height data in the field using laser range finders, following plot network protocols

- Attribution of heights to tree locations from canopy height models derived from high resolution, high point density airborne or UAV lidar or
- Attribution of height to trees through the collection of TLS data

### **2.1.6 Importance of minimising measurement error: Allometrics vs. Inventory**

The required precision of D or H will depend on the type of study. When D or H measurements are used for model development (e.g. allometric or stem volume models, or training terrestrial or remote sensors), or for monitoring small changes in attributes over time (e.g. repeat D inventory measurements of relatively small permanent sample plots in National Forest Inventories), it is essential that errors are minimised (West, 2009). This is discussed in Section 2.2.

In contrast, for stand-scale inventory studies that estimate area-based AGB at the site-level, random errors in D or H will largely cancel out as the number of measured individuals increases (Auclair, 1986; Cunia, 1986; Gertner, 1990). Hence when resources are limited, the accuracy of inventories of AGB is maximised by measuring more individuals rather than spending more time maximising the accuracy of D measurements of individuals (Paul, Larmour, et al., 2017). This is because the dominant source of random error in inventory-based estimates of stand AGB is the sampling errors (i.e. error resulting from insufficient sampling of a population, (Dot, 2016)).

Often inventory surveys to estimate stand AGB have limited resources. Therefore, maximising stand-scale accuracy by ensuring sufficient sampling intensities will require consideration of the efficiencies of measurement of D and H. For example, when measuring D, SDG or the Biltmore stick are about twice as quick as the tape (Wilson et al., 2007). Efficiency gains for some other tools tested have been less promising. For example, Kallivirta et al. (2005) found that the relative time of laser-relascope to the callipers was 0.97.

### **2.1.7 Summary and current knowledge gaps**

Field measurement errors need to be fully accounted for in the error propagation (Chapter 4). As outlined by Clark and Kellner (2012), a global database of biomass harvest plots will require a significant research commitment to improving our ability to quantify measurement errors resulting in errors in ground-based estimates of biomass, and how these may be minimised.

**To minimize uncertainties in the collection of forest biomass plot measurements, the following are recommended:**

For plot location:

- The use of differential Global Positioning System (GPS) as available, with <100km distance from base stations

- The collection of >15 Global navigation satellite systems (GNSS) points per location at plot establishment, each acquired at least 30 minutes apart
- The collection of large (minimum 1 ha) plots
- Where possible, the correction of field plot locations through the use of UAV, TLS or airborne lidar height datasets

For tree species and status identification:

- Visually tagging trees that have been measured (e.g. with tape)
- Measurement of all trees that contribute to biomass (including small trees, lianas, palms, etc.), using subplots to estimate relative contributions where logistics prevent measurement of every individual.
- Measurement and recording the status of standing dead trees
- Plots are collected following existing measurement protocols in an appropriate forest plot network for the ecosystem in question (e.g. ForestGeo, ForestPlots.net, Afritron)
- New plots be integrated into an existing plot network
- Standard protocols are adopted for classification of trees as live vs. dead
- Forest reference measurements are collected by individuals trained for attribution of trees as live/dead
- Well trained botanists are involved in plot collection
- Plots become permanent plots, integrated into an existing plot network and setup with the intention of long term measurement
- Digital copies of plot data are uploaded to digital herbaria archives that are then integrated with forest plot databases.

For diameter measurement:

- Training practitioners to follow protocols in determining appropriate height to measure stems (e.g. above buttress, for multi-stems)
- For small or irregular stems using SDG instruments
- For large (>10 cm) and/or regular stems, diameter tapes, calipers and other diameter measurement tools are all appropriate

For tree height measurement:

- Collection of height data in the field using laser range finders, following plot network protocols
- Attribution of heights to tree locations from canopy height models derived from high resolution, high point density airborne or UAV lidar or
- Attribution of height to trees through the collection of TLS data

## 2.2 Allometric Errors

Jerome Chave, Keryn Paul, Stephen Roxburgh, Dmitry Schepaschenko

### 2.2.1 Background

Tree biomass is almost never measured directly, as this implies destructive harvesting of all trees within a stand. Rather, biomass inference is usually model based: a sample of trees is destructively harvested, and the data are used to relate tree aboveground biomass to predictive variables, such as trunk diameter or tree height, through a statistical model.

In woody biomes, biomass reference datasets are deduced from tree inventories using biomass allometric models (BAMs). In tree inventories, all stems above a conventional trunk diameter are mapped, tagged, identified, and measured within one or a collection of contiguous plots (see Section 2.1). Practical issues and proper quality assessment procedures for field measurements in tree inventories are covered in Section 2.1 and Chapter 3. This chapter is concerned with the estimation of live aboveground biomass from in situ reference datasets using BAMs (S. Brown et al., 1989).

Some guiding principles prevail during the construction of biomass allometric models. They are borrowed from the principles of allometric theory, briefly reviewed here. In all living organisms, larger linear organism size implies larger mass, and this relation is called an allometry (Calder, 1984; Huxley & Teissier, 1936; Niklas, 1994). Flowering plants vary in size over eight orders of magnitude, from minute organisms less than a gram in total weight to giant eucalypt trees which are reported to weigh in excess of 200 tons aboveground (Sillett et al., 2015).

Theory suggests that tree height is allometrically related to tree dimensions. The first theoretical consideration is the pipe model theory (Shinozaki et al., 1964): trees may be represented as an ensemble of vessels running from the leaf to the fine root, and operating independently. Trees may then be seen as a bundle of vessels constricted at the trunk and expanding towards the crown and the root system. Thus a tree could be theoretically folded into a cylindrical object, and its volume would then scale as the product of total tree height and trunk cross-sectional area. Allometry has also stimulated the development of the West-Brown-Enquist theory of power-law scaling in organismic biology. Applied to plants, light-harvesting constraints imposed an isometric relationship between tree basal area (i.e. trunk cross-sectional area) and tree crown area (Enquist & Niklas, 2002). This theory also predicts that tree biomass should scale as the 8/3th power of trunk diameter.

Assuming a conical tree with basal diameter  $D$  and total height  $H$ , the aboveground tree volume is  $f \times H \times \frac{\pi}{4} D^2$ , where  $f$  is a form factor, equal to 1 if the cone is in fact a cylinder. The conversion factor from plant volume to oven-dry biomass is the wood density  $\rho$  (in  $\text{g}/\text{cm}^3$ ), defined as oven-dry mass divided by green volume. So, aboveground biomass ( $B$ ) may be deduced from the following model  $B = f \times \rho \times H \times D^2$ . This is the simplest example of a BAM,

and it may be used to convert tree trunk diameter, height and wood density into an estimate of oven-dry biomass (in kg).

In general, however, the BAM used for biomass estimation are empirical functions, and are not deduced from theoretical considerations (S. Brown, 1997; D. B. Clark & Kellner, 2012). Errors associated with the design of BAM and their proper use are discussed. Biomass estimation from tree inventories with BAM produce an estimated value, which could be the mean estimate or the most likely estimate (depending on the inferential framework), together with a confidence associated with this estimate. Here we summarize the potential issues associated with this procedure.

Biomass includes both aboveground and belowground components. Aboveground biomass is much easier to estimate than belowground biomass from tree inventories, and therefore a large part of the carbon accounting literature focuses on aboveground biomass. Belowground biomass is often inferred from aboveground biomass using stand-scale relationships (Cairns et al., 1997; Mokany et al., 2006), or tree-level relationships (Ledo et al., 2018; Poorter et al., 2015). In many temperate and tropical forests, live belowground biomass accounts for ca. 20% of the total biomass, but can be as high as ca. 60% for some trees adapted for lower rainfall (Paul et al., 2019). Biomass is sometimes defined to include both living and dead biological matter, but here we refer to biomass as live biomass. Methods for estimation of dead biomass in forest stands differ from that used from live biomass, involving protocols of coarse woody debris sampling (Keller et al., 2004), and soil organic carbon sampling (Jobbágy & Jackson, 2000).

## **2.2.2 Reference tree biomass measurements**

### *Sources of error*

Development of BAM requires the measurement of biomass of selected individual trees. Given this generally requires field measurement of fresh weights of biomass, errors in dry weights may result from sampling errors when selecting representative individuals measured, accuracy of the load cells and balances used, and errors associated with sawdust and attached vegetation like epiphytes.

Fresh weight measurements may be converted to dry weight estimates using moisture content (MC) corrections. Because any errors in the estimation of the MC correction are translated proportionally to the biomass prediction of an individual tree or shrub, care is required to ensure MC estimates are unbiased and as precise as possible. Protocols currently applied to attain MC differ in bias and precision (Paul, Roxburgh, et al., 2017), but the main source of error is sampling errors when selecting sub-samples of components (e.g. branches, bark, leaves, etc.) to represent moisture contents of those components. Errors in MC determination based on precision of the instrument, or sampling error for the individuals selected to represent the plant functional type,

were relatively minor when compared to sampling errors associated with sub-sampling components of the individual selected.

For large trees, biomass is deduced from an estimate of stem volume based on measurement of tree sections, rather than on fresh weights (Henry et al., 2010). Large trees are usually sawed into sections of 1-2 m intervals, and each component is measured, assuming that this component has a conical shape. Measurements are then used to calculate the respective branch and trunk volume. Dry mass of the plant components are then determined by multiplying volume and wood density measurements. There are measurement errors in the stem wood density, with these varying depending on the instrument used, height of measurement, and number of replicates sampled. As for errors in MC mentioned above, errors in wood density measurement are dominated by variation of wood density across sub-samples of components. Sampled wood disks are extracted from the components using a chainsaw, and are brought back to the laboratory for careful wood density determination (Fayolle et al., 2013). Stem wood density is not only a common explanatory variable for many allometric models, but is also required in to convert remote sensing (i.e. TLS or UAV) based volume estimates into biomass estimates.

An additional source of measurement error is the measurement of the carbon concentration of biomass that is then applied to convert biomass to carbon. This factor is commonly assumed to be a constant between 0.48 and 0.50, but recent work suggests this assumption leads to a positive bias in carbon stocks (Martin & Thomas, 2011). It has been recently shown that the C content in wood ([C]) is related to wood density (WD) through a negative linear relation:  $[C] = -3.5*WD+49.3$ , suggesting that [C] varies from 45.8% to 49.3% across woody plants (Martin et al., 2018). This is an important consideration when attempting to develop carbon allometric models. Since this protocol is concerned with biomass estimation, not carbon, this point is not further considered here.

#### *Examples of quantification of measurement errors*

Based on information on contributors to individual tree or shrub biomass collated by Paul et al. (2016), when measuring fresh weights in the field, the precision of load cells of varying capacity ranges from  $\pm 0.05$  to  $\pm 1$  kg, but most commonly on the order of  $\pm 0.1$  kg. However, for scales used to measure sub-samples taken for moisture content determination, the precision is usually much greater; only  $\pm 0.001$  to  $\pm 0.1$  kg.

Errors associated with MC correction have been quantified by exploring MC measurements of 1396 individuals (trees and shrubs) of various sizes (Paul, Roxburgh, et al., 2017). Using a Monte-Carlo analysis this study found MC estimates may be based on at least the bole and crown components, with bias resulting if MC is based on stem wood only, particularly in young (or small) individuals. Little gain in accuracy was attained with more intensive sub-sampling (e.g. into foliage, twig, branches, bark, and stem wood components). Variation in MC of aboveground biomass can be substantial (CV > 15%) when considered across individuals of various sizes (or age) from across differing sites (or climates). However to minimise bias, Paul, Roxburgh et al.

(2017) found it was important to undertake MC sampling at each study site, and to stratify sampling among-individuals by both appropriate taxonomic grouping (e.g. plant functional type) and age-class. For a given plant functional type-by-size (or age) strata at a given site a precision of about 4% coefficient of variation of the average MC estimate can be achieved with intensive within- and among-individual sampling.

Existing reference datasets for BAM construction rely on legacy data, a compendium of tree harvest data collected over decades, from different operators, and with different field protocols. Thus, field measurement errors are not always well documented. For example, forestry projects sometimes report the merchantable biomass, rather than total biomass. Also, the tree stump may be ignored from the aboveground biomass total. As a result, error associated with legacy data is not always quantifiable. For recently developed reference datasets for BAM construction, error sources associated with field measurements are generally well documented. In particular, protocols for measuring wood density correctly have been published (Williamson & Wiemann, 2010) and studies have explored the minimal sampling size necessary to provide accurate estimates of wood density (da Páscoa et al., 2020; Picard et al., 2012).

#### *Recommendations for validation*

In the development of new BAM it is important that reference destructive harvest datasets be as accurate as possible. Adhering to a fixed set of measurement protocols ought to be a prerequisite for new BAM. Destructive measurements of large trees in particular are at a premium to better-define these models. If trees, or tree components, are directly weighed, errors in fresh weight measurements of biomass should be minimized by ensuring that load cells used in the field have precision  $\leq \pm 0.5$  kg, and that operators are well trained in the use of these load cells. For the conversion of fresh weight into dry weight, **it is recommended** that MC determination be derived at each study site for each strata. **It is recommended** that six individuals be randomly sampled, and partitioned and sub-sampled into crown and bole components. For large trees, measurements are based on volume estimates and conversion into dry weight based on wood density measurements. Volume estimation should be conducted carefully on tree components. For conversion of wood volume into dry weight, **it is recommended** that the same subsampling be conducted as for MC determination.

Today, volume estimation based on TLS technology would be **a recommended alternative** to conical approximations (see Section 2.3). This could greatly facilitate the calibration of new allometric models, or even implement model-free methods of biomass estimation. However, TLS also suffers from practical issues in leaf-on conditions, with laser occlusion diminishing the quality of tree reconstructions, TLS cannot detect hollow stems, which are frequent in old-growth forests, and finally TLS measures volume, not biomass, and wood density is a crucial parameter in biomass estimation. For these reasons, advances in the routine collection of TLS remains a crucial area of research, and TLS should be acquired in addition to, but not in replacement of, traditional mensuration and allometric models.

## 2.2.3 Tree biomass estimation from allometric models

### Sources of error

Trees are widely structurally variable, based on their life histories (e.g. from diseases, storm damage, drought), and local growing conditions (e.g. proximity to neighbours). We do not expect that a model will precisely estimate the biomass of every single tree given this natural variability. However, if the model has systematic prediction error, then sample estimates of the plot biomass are likely to improve as the number of sampled trees increases. Thus, even if the estimation of individual trees may be imprecise, biomass estimates of stands may be precise.

BAMs are often reported in the form of regression models, and the fit of model parameters is obtained from a training dataset (reference tree biomass measurement, see Section 2.2.1). A classic formulation of an empirical biomass model is:  $B = F(D, H, \rho)$ , where  $F$  is a function of the three variables trunk diameter ( $D$ ), total tree height ( $H$ ) and wood density ( $\rho$ ). Theory suggests that a realistic model is:  $B = f \times (\rho \times D^2 \times H)$ , where  $f$  is a parameter. Sources of error associated with this procedure depend on how comprehensive the reference tree biomass dataset is.

Simpler models have also been proposed. Since total tree height is seldom measured, it has often been proposed instead to use a model of the form:  $B = a \times D^b$ , where tree  $B$  depends only on the trunk diameter, and where  $b$  is a parameter (power-law exponent). Note that a mathematically equivalent formula is obtained by taking a logarithmic transform of both sides of this equation:  $\ln(B) = \ln(a) + b \times \ln(D)$ . This algebraic log-transformation is the basis for the construction of many biomass models. Setting  $Y = \ln(B)$ ,  $X = \ln(D)$ , the above becomes a linear model:

$$Y = a' + b \times X, \text{ where } a' = \ln(a)$$

This model has the desirable property that  $B$  goes to zero as  $D$  goes to zero (if  $b$  is a positive parameter). The AGB of a single tree must be associated with an error term:

$$Y = a' + b \times X + \varepsilon$$

The error term  $\varepsilon$  is often assumed to be a normal error with no bias, and is uniquely determined by its spread, called the standard deviation  $\sigma$ : a large standard deviation means that random error is large, and precision low. There is no *a priori* reason for assuming that different allometric models should be applied to trees of different size classes: piecewise models inevitably come with discontinuities at the domain boundaries. Examples of classic formulations for BAMs are reported in Table 2.2.

**Table 2.2 Example formulations of biomass allometric models**

Biomass allometric model	Reference
$\ln(B) = \ln(a_1) + b_1 \times \ln(D) + c_1 \times (\ln(D))^2 + d_1 \times \ln(\rho)$	Alvarez et al. (2012); Fayolle et al. (2013)
$\ln(B) = \ln(a_2) + b_2 \times \ln(D) + c_2 \times \ln(H) + d_2 \times \ln(\rho)$	Chave et al. (2005); Alvarez et al. (2012)

$\ln(B)=\ln(a_3)+b_3 \times \ln(\rho \times D^2 \times H)$	Chave et al. (2014)
$\ln(B)=\ln(a_4)+b_4 \times \ln(D) + d_4 \times \ln(\rho)$	Chave et al. (2005); Alvarez et al. (2012)
$\ln(B)=\ln(a_4)+b_4 \times \ln(D)$	Paul et al. (2016)

The linear model returns the log-transformed AGB of a tree. Back-transforming the model above for a given tree  $i$  yields the following result:

$$B_i = \exp(Y_i) = \exp(a' + b \times \ln(X_i) + \varepsilon_i)$$

The complication is that if  $\varepsilon_i$  has zero mean (i.e., is unbiased),  $\exp(\varepsilon_i)$  is no longer unbiased and a correction factor is required. Clifford et al. (2013) explored the relative performance of nine different correction factors in terms of correcting for this bias, but a robust correction factor that is commonly applied is proposed; the Baskerville correction factor (Baskerville, 1972). This correction factor depends on the magnitude of random error, which is quantified by  $\sigma$ , and writing  $a'' = a \times \exp(\sigma^2/2)$ , the biomass of tree  $i$  may be estimated using the following equation:  $B_i = a'' \times (D_i)^b$ .

For some applications, the biomass allometric model may be biased, that is, systematic under- or over-estimation (JCGM, 2008). This may be because the model is used outside of its normal range of calibration, or because the model has been calibrated using too few destructively sampled trees (Roxburgh et al., 2015). If an allometric model has been calibrated using a sample of small trees, using it outside its range of calibration, i.e. to estimate large trees may lead to bias (e.g. Duncanson, Rourke, et al., 2015). If an allometric model has been calibrated using only a few destructively harvested trees, typically less than 20-50 trees, it is more likely to be biased than a model calibrated based on hundreds or thousands of destructively harvested trees (Roxburgh et al., 2015). Producing biomass estimates from a biased allometric model results in potentially large systematic errors in remote sensing products and carbon stock estimates.

### *Examples of quantification of measurement errors*

Then ordinary least squares regression permits the estimation of three model parameters:  $(a', b, \sigma)$ . Any statistical software can input a dataset with measured values of  $D$  and  $B$ , take a logarithmic transform of these values, and construct a best-fit regression by a linear model. In the R statistical computing platform, the command for linear model construction is `lm()`, and the outputs include the model parameters  $(a', b)$  and the random error estimate  $\sigma$  (stored in the variable `sigma`). The standard deviation is the canonical metric to represent precision in a linear model.

Note that in larger trees, biomass estimation has a larger standard deviation. This is related to the multiplicative nature of allometry that is often used to represent the dependency between biomass and biometric variables (see below for mathematical details). However, the relative error (standard deviation divided by the expected value, also called coefficient of variation) does

not strongly depend on tree size. One analysis suggests that the relative error in biomass estimation of a single tree can be as large as 50% (Chave et al., 2014). However, detecting the magnitude of a size dependency in prediction of biomass is crucially dependent on reference biomass data (Burt et al., 2020). However, because the errors are uncorrelated across trees, stand-level error declines rapidly as stand area increases (i.e. as the number of trees included in the sample increase, since biomass density is obtained by summing individual tree biomass over a given area; (Réjou-Méchain et al., 2014). Most carbon accounting programs do not demand that individual trees be estimated accurately, but that plot-level biomass density estimates be accurate.

To calibrate a BAM, an important practical question is how many trees are needed to estimate the parameters to a good precision. A study of this question based on empirical datasets (Roxburgh et al., 2015) suggests that a minimal number of trees is 25, but that good performance is achieved only if the destructive sample reaches or exceeds 100 trees. Under the assumptions of allometric model form, combining samples from studies that use different measurement methods into a single biomass allometric model, can lead to large model uncertainty (Burt et al., 2020). Careful consideration should be paid to how many trees were destructively sampled to develop a model, how well the sampled trees used to develop the model match the diameter distribution in the population of trees to which it is applied, and how well the model can estimate the biomass of an independent set of sample trees. To avoid developing local allometric models, one can rather use already existing destructive biomass data. Much useful destructive biomass information is already available in the literature (Clough et al., 2016; Paul et al., 2016), (see also Chave et al., 2014; Radtke et al., 2015). The literature should be combed before new fieldwork is done or further stratification is decided.

### *Recommendations for validation*

Validation of BAM requires the availability of separate biomass tree reference datasets to be used at validation stage only. A common practice is to validate the model by partitioning biomass tree reference data into a training set and an independent validation set. **It is recommended** that the validation dataset has a similar tree-size structure as the calibration set, so users should ensure that validation includes both small and large trees. This is crucial because large trees hold a disproportionate share of biomass, and destructive harvest samples are often smallest for the largest tree size classes. Paul et al. (2018) showed that independent sample size of  $N \leq 15$  frequently (37–46% of the time) provides insufficient power to avoid incorrectly accepting “validation” (type II errors). They recommended at least 50 trees be sampled for each species.

Validation of the model predictions should be based on clearly defined metrics. Paul et al. (2018) recommended that an equivalence test may be applied to determine if the minimum detectable negligible difference between the reference model and the new independent data is <25% (or whichever threshold is deemed acceptable). If so, the new data set may then be combined with existing data to refine a generalised model, which may then be applied with confidence. If not,

then the resources expended need not be wasted as the sample size is sufficient to develop a new model suitable for application to the specific species sampled.

Therefore, it is essential to validate allometric models based on independent destructive harvest data. Unfortunately, many published biomass models do not follow any standard validation procedure and thus selecting the best performing allometric model for application in a given geographic domain is often left to speculation.

Information on how and why to select a particular BAM is seldom provided. Unless objective criteria are available, confirmation bias can result in cherry-picking of models. **It is therefore also recommended** that users should report procedures and criteria used for selecting existing models, and model diagnosis and validation (Sileshi, 2014).

## 2.2.4 Selecting suitable biomass allometric models

### *Sources of error*

Estimation of biomass from forest inventories is often based on locally derived BAM, because it is perceived that a local model is more accurate, reflecting the peculiarities of the study forest of forest type. Likewise, it is generally assumed that a species-specific BAM is a better model than a species-independent BAM. For instance, in the temperate zone, it has been customary to develop species-specific models, e.g. different models for oak, poplar, birch or beech. Generalized (regional to global) BAM are often considered as being less accurate than local species-specific models. Is it preferable to use a few generic biomass estimation models, applicable to a wide range of forest types, or many biomass estimation models, each constructed to one plant functional type, one forest type or even a single species?

### *Examples of quantification of measurement errors*

Tree biomass estimation based on trunk diameter, total tree height and wood density should in theory depend on a single estimated parameter, the form factor (see 2.2.1). The form factor is unlikely to vary greatly across forest types, because this factor is constrained mechanically, and it is related to the tapering of trunks, which has been classically measured in forestry (Radtke et al., 2015). This suggests that a single model could be used across tree species in the tropics. A test of this hypothesis has been conducted across tropical forests, and confirms the idea that a single biomass model can be used across the tropics (Chave et al., 2014). Recently, a test of this hypothesis has been conducted in four countries of tropical Africa (Fayolle et al., 2018). Results based on this large independent dataset (over 600 destructively harvested trees) confirm that the biomass model of Chave et al. (2014) shows a low bias. Although more comparable studies are desirable to assess model accuracy, designing destructive harvest experiments for validation of allometric models is difficult, time consuming and expensive, especially when large trees are included in the sampling strategy (which should be the standard practice). Such experiments should be carefully designed and coordinated.

The web platform GlobAllomTree (<http://www.globalometree.org/>), launched by FAO in 2013, collates over 13,000 BAM from all sorts of studies (local, regional, national), but often based on small destructive harvests (less than 25 trees, Henry et al., 2010), making it difficult to assess the accuracy of individual models. Thus, while the model root mean square error (RMSE) can be estimated from the modelled structure of the data (Henry et al., 2013), a validation of the prediction error is difficult for most of the reported models. If the set of species is limited, it is however possible to deduce generalized BAM from the combination of many local and species-specific BAM, as was done for European forest tree species (Forrester et al., 2017).

### *Recommendations for validation*

**It is recommended** that allometric model quality be carefully assessed, and that models that do not specify the range of validity in the independent variables, size of calibration sample, geographic domain of training data, and the associated random error metric, should not be used. While one global allometric model may not be reasonable, given for example differences between tropical forests and temperate conifer forests, more research into the accuracy of generalized allometries is required. In particular, the extent to which broadleaf trees and conifers vary in their biomass allometry should be better studied. Once biomass models are carefully validated, their selection for specific sites should follow a rigorous procedure (Pérez-Cruzado et al., 2015).

For biomass estimation of tropical forest stands, **it is recommended** that the R package BIOMASS be used to predict AGB from inventory measurements (Réjou-Méchain et al., 2017). This package is called by several other packages dealing with different data formats. It possesses default BAM options for tropical forest AGB prediction that can be used to estimate biomass with traditionally measurable attributes (D, H, WD), and it also provides uncertainties based on knowledge of the main error components in AGB prediction for tree inventories. New BAM could theoretically be provided by the user, such as, for instance, BAM specific to Australian forests (Paul et al., 2016), for forests of North America (Chojnacky et al., 2014), or for forests of Russia (Schepaschenko et al., 2017). However, the BIOMASS package would need to be updated to include these. To implement the R package BIOMASS with other BAM, raw data used to produce the BAM should be provided as an input.

## **2.2.5 Biomass expansion factors**

### *Sources of error*

Many methods in temperate forestry attempt to infer aboveground biomass from harvestable biomass or from harvestable volumes, the classic currency in forestry. The forestry sector has implemented allometric principles since the 18th century to establish stand volume tables, which

quantify merchantable volume of forests. Stand volume tables have been developed to a high level of detail, and published models depend on species, soil fertility, and climate (Jenkins et al., 2003; Schepaschenko et al., 2017; Zianis & Mencuccini, 2004), so procedures for merchantable volume accounting are complex. Because much data is available on harvestable volumes from the forestry sector, valorising this information is desirable.

This method seeks to estimate the total AGB of a tree by measuring only its merchantable log volume, excluding branches and leaves (or needles). It is sensible to ask whether there should be a simple scaling relationship between branch biomass and stem biomass. From that knowledge one computes the ratio of AGB divided by stem biomass, also known as the Biomass Expansion Factor (BEF).

#### *Examples of quantification of measurement errors*

Measurements of trees across size classes suggest that the BEF is proportionally higher in saplings than in mature trees. This suggests that attempts to model the BEF should be size-dependent. This may not be a major issue in even-aged plantations, but could be problematic for mixed and/or mature forests.

Also, trees growing in open conditions (e.g. in open woodlands, or in agropastoral landscapes) tend to branch off more than trees in closed-canopy forests or in plantations. Trees branching off earlier tend to have more of their biomass in branches proportional to the total biomass, hence a higher BEF.

For low-diversity forests, and where extensive prior knowledge is available on BEF, the BEF-based inference, which considers site index and tree density (e.g. Schepaschenko et al., 2018), has advantages compared to BAM. For instance, the site index is related to wood density, which may vary across sites within the same tree species. Likewise, tree density relates to canopy features: sparse trees invest more biomass to branches, compared to dense forest trees.

#### *Recommendations for validation*

AGB appears generally to be more directly related to tree biometric variates and forest structure as captured by tree inventories than to merchantable log volume, implying that estimating tree biomass from a BAM and a tree inventory is less error-prone than the alternative based on biomass expansion factors. **It is therefore recommended** to predict AGB from forest inventories combined with BAM, rather than based on BEF. However, in areas where extensive forestry expertise is available, and for even-aged plantations, and also if BEF are validated extensively across the range of forest types and conditions, the combination of merchantable log volume and BEF could be an alternative.

## 2.3 Terrestrial laser scanning & UAVs

Kim Calders, Nicolas Barbier, Harm Bartholomeus, James Kellner, Felix Morsdorf, Crystal Schaaf, Atticus Stovall, Christian Thiel

### 2.3.1 Background

New developments in remote sensing, such as the use of Terrestrial Laser Scanning (TLS) techniques and the use of Unmanned Aerial Vehicle (UAV) platforms, can help us with the validation of AGB products at local to regional scales. The potential of TLS for forest monitoring was first demonstrated more than a decade ago, but has not yet reached its full potential, for the reasons outlined above. Newnham et al. (2015) & Anderson et al. (2016) provide a full review of the development of TLS as a forest measurement tool. The utilization of UAVs for the acquisition of ultra-high resolution (<1 m) imagery and laser scanning data has heavily increased during the past five years.

TLS is a ground-based remote sensing system that can measure three dimensional (3D) vegetation structure (i.e. the size and location of canopy elements) to centimetre or even millimetre accuracy and precision. The location of points in 3D space is done by transmitting laser energy and analysing the reflected energy as a function of time. TLS measurements are essentially not limited in azimuth and zenith angles. This is an important advantage compared to most airborne and satellite based instruments that generally have a restricted viewing angle range.

Point clouds from UAV platforms can be generated directly through laser scanning (LS) or indirectly through structure from motion (SfM) from image data. In the latter case the overlap between images enables stereoscopic image processing resulting in 3D point clouds representing the forest structure (Hernández-Clemente et al., 2014; Lisein et al., 2013; Puliti et al., 2015; Suomalainen et al., 2014; Zarco-Tejada et al., 2014). The motivation to use UAV-SfM 3D data is the rapid delineation of several forest parameters such as canopy height, canopy cover, tree location, number of trees, tree density, tree height, stem volume, and tree species for continuous forested areas of several hectares for a relatively low cost compared to the UAV lidar systems. However, the success of using UAV-SfM to monitor forest structure will depend on the openness of the forest canopy. UAV-SfM data are less precise over gaps and can only describe the top of the canopy, whereas UAV-LS has a greater canopy penetration depth and better precision (Roşca et al., 2018).

Traditionally, allometric models are used for estimating AGB at local levels (see Section 2.2). Typically, the volume or AGB of trees in the calibration data of allometric models is related to their DBH and height. The calibration data that underpin these allometric models is often skewed towards smaller trees, which can result in large uncertainties for bigger trees (Calders, Newnham, et al., 2015). Destructive harvesting is expensive and not always practical or desirable. In this

chapter we describe how 3D data from TLS and UAV platforms can contribute to the generation of AGB reference datasets.

**Figure 2.1** Slice of a forest with old Beech and Oak from the same perspective, acquired in the Netherlands with TLS (Riegl VZ-400)(top), UAV-LS (Riegl VUX-SYS) (middle) and UAV-SFM. The number of points in these slices are 69,547,639 (TLS); 5,396,682 (UAV-LS) and 96,229 (UAV-SFM)

## 2.3.2 Plot scanning protocols

### 2.3.2.1 Data collection

TLS sensors are usually tripod mounted and record single scans from a fixed location. As such, scans are affected by occlusion, i.e. the near objects in the forest can obscure objects further from the scanner. The effects of occlusion can be significantly reduced by obtaining data from multiple scan locations. Multiple single scans made at different locations can be co-registered (to within mm accuracy depending on instrument and environment) using high reflectivity targets that act as tie-points between different scans (Wilkes et al., 2017). Recent work on reflector-less

registration algorithms is promising (Kelbe et al., 2016) and a new range of commercial scanners (Leica BLK360 and RIEGL VZi-series) provide onboard registration without the need for targets. Currently, more testing (i.e. quantifying the effect of ecosystems, instrument characteristics and sampling design on the performances of these algorithms) is required before it is recommended to use these in an operational context.

Since UAV-LS is a relatively new and rapidly developing technology, there is less expertise on the best acquisition settings. The point density depends on the frequency of the scanner in combination with the forward flying speed, number of flight lines and altitude, which can all be varied during flight planning. Therefore, acquired point densities vary from 50 pts/m (Wallace et al., 2012) to 100-1500 pts/m (Brede et al., 2017; Jaakkola et al., 2017) to >3000 pts/m<sup>2</sup> (Brede et al., 2017; Morsdorf et al., 2017). Brede et al. (2017) showed that it is essential to include scan angles >30 degrees of nadir to get enough returns on the tree stem (see figure 2.2). Further, using a system capturing multiple returns is essential to measure the below canopy structure and allow for individual tree modeling. This enhanced penetration depth due to multiple returns is a critical advantage of (some) UAV-LS systems over UAV-SfM in the context of generating AGB reference data from whole-tree volume reconstructions.

**Figure 2.2** Scan angles distribution for points on the stem at DBH. Especially scan angles of >30 degrees contribute (Brede et al., 2017)

### 2.3.2.2 Instrument requirements & limitations

A range of scientific and commercial scanners are currently available. Whereas airborne lidar systems have been used in forest measurements since the mid-eighties (Nelson et al., 1984), the first commercial terrestrial laser scanners came to the market in the late 90s with instruments such as the RIEGL LMS Z210 and CYRAX 2200. The first TLS instruments used a time-of-flight ranging principle, with phase-shift based ranging instruments following soon after. The

commercial instruments were (and still are) generally developed for precision mapping and survey applications where extended targets (i.e. structurally continuous surfaces) dominate e.g. urban areas and/or mineral and petrochemical exploration. This has implications for their use in forest applications, where many laser hits are partial, and/or from softer targets (i.e. structurally fragmented or dispersed surfaces) with anisotropic reflecting surfaces such as leaves or needles and bark. Of the scientific (i.e. non-commercial) scanners, the Echidna Validation Instrument was one of the first laser scanners specifically designed to monitor vegetation (Strahler et al., 2008), more recently followed by the full waveform Dual Wavelength Echidna lidar (DWEL; Li et al., 2018) and the Salford Advanced Laser Canopy Analyzer (SALCA; Danson et al., 2014; Hancock et al., 2017). Table 2.3 provides a summary overview of commonly used TLS instruments in vegetation monitoring. Small robust instruments are increasingly being used in adverse environments, including the scientific Compact Biomass Lidar (CBL; Paynter et al., 2016) and the Leica BLK360. Newnham et al. (2012) provide a detailed independent comparison between some commercial scanners and evaluated their performance for measuring vegetation structure.

**Table 2.3 Examples of TLS instruments used to assess forest structure. Non-commercial instruments are shown in grey.**

Major Instrument Categories	Short-range TOF + large beam divergence	Mid-range TOF + medium beam divergence	Long-range PS + small beam divergence	Long-range TOF + medium beam divergence + low noise	Mid-range Dual Wavelength + medium beam divergence
Cost	\$	\$	\$\$	\$\$\$	\$\$\$
Ideal Forest conditions	+ Sparse/simple forests + Remote areas	+ Sparse/simple forests + Remote areas	+ Leaf-off or structurally simple forest stands + Remote areas	+ Best in tall/dense forests	+ Accessible, structurally simple forest stands
Optimal Forestry Applications	+ Rapid assessment + Robust + Cost-effective forest structural metrics	+ Rapid assessment + Cost-effective forest structural metrics	+ Finely resolving small branches	+ Finely resolving small branches + Potential for full waveform applications	+ Leaf-wood separation + Biochemical properties + Improved vertical foliage distribution + Potential for full waveform applications

<b>References</b>	Paynter et al. (2016; 2018)	Disney et al. (2019)	Liang et al. (2015); Pyörälä et al. (2018)	Bienert et al. (2018); Tian et al. (2019)	Danson et al. (2018); Schofield et al. (2016)

In recent years, the use of UAVs for the acquisition of close range remote sensing data has emerged (Kellner et al., 2019). Once the hardware is purchased, images can be recorded almost at any time and at low cost. The overlap between the images enables stereoscopic image processing (UAV-SfM), the delineation of high density 3D point clouds and the generation of seamless image mosaics. Due to regulations and technical limitations, at present, UAVs are used for the acquisition of local data only. Considering the maximum distance of 500 m between pilot and UAV (legal requirement in many countries) an area of approximately 75 ha can be covered during one flight. A new development is the usage of drones as lidar platforms. One of the first off-the-shelf systems – the RiCOPTER - was released by RIEGL. As the drone can be operated at very low flight speed, great overlap between the tracks and variable flight altitude, the resulting sample point density is very high. Another interesting feature is the wide scanning angle of the small footprint lidar RIEGL VUX-1UAV sensor. A number of alternative (lighter and cheaper) options are now available on the market, with increased operational versatility (e.g. Mdlidar1000 by Microdrones, DJI Matrice Series Livox with Mid-40 or Mid-100, Tron F9 VTOL fixed wing, Vapor 55 UAV helicopter, lidar hardware by YellowScan). Vertical tree structures such as stems can be sampled with a high density of pulses, which is of interest for forestry applications. Such systems allow users to obtain up-to-the-minute data which is of particular importance when solving specific local and regional issues in which a user defined spatial and temporal resolution needs to be met for the generation of reference datasets. Table 2.4 gives a comprehensive overview of typical UAV systems for monitoring forests. Please note that quadcopters are preferred for forest applications of stereographic imaging, since they allow for oblique (non-nadir) views of the canopy.

**Table 2.4 Selection of UAV Systems**

<b>Mission/Sensors</b>	Quantum systems TRON Quadcopter fixed-wing hybrid (platform, gimbal, various camera systems)	Geocopter X8000 Octocopter (platform, gimbal, various camera systems)	DJI Phantom IV Pro Quadcopter (platform, gimbal, installed camera system)	RiCOPTER VUX-SYS (platform with integrated VUX-1UAV lidar scanner)	Quantum systems TRON Quadcopter fixed-wing hybrid (platform with integrated YellowScan “SURVEYOR” lidar scanner)

**2.3.2.3 Plot establishment**

Sampling strategies for geometric modelling of AGB reference sets should aim for minimal occlusion and uniform point density in order to provide consistent point cloud quality throughout the plot. This may require sampling over a larger area than the plot size, particularly for smaller plots (< 1 ha). When designing a sampling strategy for capturing data at plot level, it is important to consider that the resulting point cloud needs to:

1. Capture a large proportion of the target canopy to:
  - a. Be spatially representative and account for occlusion; and
  - b. Sample a wide range of view angles
2. Have a uniform point density across the scanning domain.
3. Be easily co-registered/aligned with the required degree of accuracy.

For terrestrial lidar data acquisition, **it is recommended** that the overall scan pattern forms a continuous “chain” where each scan location is linked to other (neighbouring) scan locations. A number of different configurations have been trialled dependent on stem and understory density. Different instruments and environments will require a custom-tailored plot setup. As a general rule, we advise to take into account the three recommendations from above to ensure good data quality. Wilkes et al. (2017) gives detailed recommendations for a high-end RIEGL VZ-instrument. For example, when understory vegetation is dense a higher resolution sampling grid has been used e.g. 10 m x 10 m, to ensure adequate sampling of the canopy through the understory as well as occlusion of adjacent scan locations; whereas, if the understory is more open, a 20 m x 20 m sampling grid has been used. In general, the number of scan locations is an important consideration, particularly in tall or dense forest canopies. A sparse sample grid can save time and resources, particularly for large area field campaigns and monitoring programs. However, this may cause issues with co-registration and result in heterogeneity in point density across the plot. Furthermore, decreasing the sample density significantly decreases the fidelity of the branching structure towards the top of the canopy and potentially leading to more uncertainty in derived outputs sensitive to these canopy components (figure 3). Recent efforts have been focused on analyzing data acquisition while in the field, to reduce the impact of occlusion by adapting the scanner placement dynamically (Paynter, Genest, Saenz, et al., 2018). In many National Forest Inventories, circular plots are a standard. In France, where TLS is increasingly integrated in the NFI, with ~2% of the plots scanned, about 10 scans are performed within the 15 m radius plots, following two concentric circles (at around 6 and 10 m from center), with the reference targets scattered within the inner circle (C. Vega, personal communication, n.d.).

To achieve good quality UAV-LS data, a wider range of view angles is more important than a higher point density (Brede et al., 2017). Building on the expertise with ALS and TLS systems, minimizing occlusion for UAV-LS is best done by using more flight strips (best in a crossed pattern) to provide more observational angles into the canopy (Morsdorf et al., 2017). Long-endurance platforms, such as the upcoming Aeroscout Scout B-330 (3 hrs flight time) allow for the sampling of 100 hectares. However, regulations are limited in many countries and often do not allow UAVs to fly too far from the launch spot. Another limitation is the need for a big enough gap for take-off and landing, which is often not available in dense forests.

Figure 2.3 A comparison of mean nearest neighbour distance (nn) for points that comprise an individual tree derived using 10, 20 and 30 m grid sampling densities. (Left column) The location

of sample points and location and extent of the target tree. (Middle column) Point cloud representations of the sampled tree including mean nearest neighbour distance for different canopy heights. (Right column) Subset 3 m x 3 m x 3 m voxels for different areas of the tree, locations are identified in the middle column. The tree has been extracted from the Ankasa AfriSCAT plot in Ghana [Figure from Wilkes et al. (2017)].

## 2.3.3 Data processing protocols

### 2.3.3.1 Point cloud to volume estimates

The combination of multiple individual terrestrial lidar scans using registration targets significantly reduces occlusion. After the registration of individual scans to co-registered point clouds, estimating AGB requires:

- (i) segmentation of the full point cloud into single trees (+ leaf vs. wood segmentation);
- (ii) geometric modelling to estimate volume; and
- (iii) conversion of volume to AGB using wood density.

**Figure 2.4 Example of a co-registered and segmented TLS point cloud from Wytham Woods, UK.** Single trees extracted for a 20 x 100 m transect. Data captured with a RIEGL VZ-400 instrument and tree extraction was done with the *treeseq* algorithm (Burt et al., 2019). (a) Top view; (b) Side view

Burt et al. (2019) describes an open-source software (*treeseq*) for the near-automatic extraction of tree-level point clouds from larger area point clouds (see figure 4). They demonstrated an automated segmentation success rate of 70% in dense tropical rainforest and 96% in a more open forest. Other methods such as Raumonien et al. (2013), Trochta et al. (2017) or Zhong et al. (2017) offer alternatives, but are generally limited to application in structurally simple and sparse forest types.

Several reconstruction algorithms have been developed to produce full 3D reconstructions of tree structure from single-tree point clouds. These so-called Quantitative Structural Models (QSMs) provide topologically-connected estimates of tree trunks and branches down to finescale (cm), allowing for straightforward calculation of volume. Dassot et al. (2012) used simple geometric fitting to model the woody structure of individual trees, whereas Hosoi et al. (2013) used a voxel-based approach. Both these approaches require a substantial amount of manual input. Côté et al. (2009, 2011) developed an automated algorithm that models a free form circular cross-section woody model based on intensity filtering of the lidar returns. Fine branching and leaves are added to the woody structure based on the low intensity returns. All these methods suffer from the difficulty of assessing the accuracy of the resulting reconstructed QSMs. Disney et al. (2012) developed a 3D modelling approach to overcome this, by using 3D simulated TLS data from tree models whose structure and volume is known a priori. This approach was applied by Raumonen et al. (2013), who describe a reconstruction method based on local patch fitting to produce cylinder-based QSMs. Hackenberg et al. (2015) developed a slightly different approach to QSM reconstruction, but volume estimates agree well with Raumonen et al. (2013). Momo Takoudjou et al. (2018) and Gonzalez de Tanago et al. (2018) showed that the obtained QSMs could be used to obtain unbiased estimates of volume and biomass, even for very large tropical trees, allowing for the non-destructive calibration of allometric models. Care still needs to be taken to obtain unbiased estimates (Momo Takoudjou et al., 2018), as cumulating automated algorithms for tree segmentation, leaf v. wood segmentation and finally reconstruction can sometimes result in inconsistencies between reconstructed trees and the original point cloud. It is thus still advisable to maintain human supervision and quality control in the processing of dense forest stands.

**Fig 2.5** Point cloud (left) and corresponding QSM (right) using the method of Raumonen et al. (2013).

For the operational delineation of UAV derived point clouds several commercial and open source software packages are available. This kind of software commonly comprises bundle adjustment and SfM algorithms. Though, for commercial software the code is not published. Based on the

point clouds Digital Surface Models (DSMs) and after vegetation filtering Digital Terrain Models (DTMs) can be delineated by rasterizing the point clouds. Using UAV-based DSMs and DTMs, e.g. the canopy height can be precisely measured (Thiel & Schmullius, 2017). For the delineation of elevation data products based on stereophotogrammetry and related approaches the same points or image objects must be identified and precisely detected in all overlapping images. In particular in areas with low contrast (e.g. snow covered area) the number of reliable points can be very low. In such areas a large number of Ground Control Points (GCP) is required which causes increased production costs. In general, the number and positional accuracy of detectable points per unit area increases with increasing spatial resolution. A high point density permits small raster cells of the final elevation model. In areas with a very low point density interpolation might be required as an intermediate step. Morsdorf et. al (2017) found that UAV-LS data has sufficient quality to model tree stems and large branches, but does not resolve fine branches. Using QSM algorithms to model individual trees from UAV-LS data and quantifying their uncertainty need further testing since these algorithms are developed for TLS data.

### **2.3.3.2 Repeatability**

One of the challenges of interoperability is the commercial confidentiality of instrument internal performance properties, making interoperability difficult. Calders et.al (2017) compared three TLS instruments from the same make and model (RIEGL-VZ400) and found that range accuracy between instruments is comparable, but that the radiometric calibration is instrument specific. Calders, Schenkels et al. (2015) reported a relative standard deviation in effective wood area index from repeated leaf-off scans of 0.72% (including removing and setting up the tripod and same instrument again over multiple days).

Both laser based and stereogrammetry based UAV approaches aim at a digital 3D representation of 3D real world objects. Both approaches collect a finite number of discrete samples. In other words, the level of detail representing these real world objects is limited. Moreover, repeated sampling will not result in the same samples, even for unchanged objects (e.g. vegetation has not moved etc.). Several factors are responsible for this shortcoming. The most obvious one is related to the varying acquisition geometry caused by varying acquisition positions of the UAV at the different campaigns. Therefore, the sample based models of the real world objects will have low reproducibility, deviating among measurements depending on the sample position, with the magnitude of this random error depending on the sampling rate.

However, depending on the research question or application, this drawback does not necessarily harm the usefulness or applicability of UAV-SfM or UAV-LS based point data. As found in previous studies (Brede et al., 2017; Morsdorf et al., 2017; Thiel & Schmullius, 2017), a point density of several hundred to thousand points per m<sup>2</sup> can be achieved with UAV-SfM and UAV-LS techniques. In terms of the delineation of a detailed canopy height model for automatic tree detection the sampling density is more than sufficient, as all required elements (e.g. tree tops, gaps between crowns) are captured with great detail. As in various (repeated) acquisitions the same level of details is preserved, equal results can be expected.

Repeatability becomes a critical issue if the lidar point density is low. This can be true for airborne lidar systems which are flown with a typical nominal point density of below approximately 4 points per m<sup>2</sup> (Leitold et al., 2015). These systems may miss important details such as tree tops, or ground elevations under dense canopies, resulting in an underestimation of single tree or canopy height depending on sensor specification (Disney et al., 2010). Discrepancies in multi date airborne acquisitions can also lead to difficulty in interpreting change (e.g. Duncanson & Dubayah, 2018). Accordingly, the data acquired at two different UAV-LS campaigns might differ in a way that adds uncertainty to change estimation. This can include the detection of single (small) tree removal or the measurement of individual tree growth. For instance, Thiel et al. (2017) showed that a point density of 4 points per m<sup>2</sup> is not sufficient to automatically detect small trees, even in a simply structured forest. By using UAV-SfM data with a much higher point density the detection rate was obviously increased.

#### **2.3.3.3 Stem map errors (linking to census measurements)**

Linking existing census data to stemmaps derived from TLS or UAV data is important for determining the species of trees and using species-specific wood density for the conversion of volume to AGB. However, the accuracy of census coordinates is generally not as good as direct 3D measurements. Calders et al. (2018) manually compared census and TLS derived stem maps, achieving a link-success of 86% in a deciduous forest in the UK. Linking large trees is generally easier than smaller trees or multi-stem trees.

#### **2.3.3.4 Characterization of errors and uncertainties**

Methods have been developed to estimate more familiar forest monitoring properties such as DBH and tree height directly from the 3D point cloud. DBH and tree height are important structural measures (Section 2.1) that are historically used to predict AGB based on empirical allometric relationships (Chave et al., 2004, 2014). Numerous studies have estimated DBH using least square fitting from TLS point clouds. Tansey et al. (2009) reported a root mean squared error (RMSE) of 0.019 to 0.037m and analysis in Calders, Newnham et al. (2015) showed a RMSE of 0.0239 m. Stovall et al. (2017) estimated DBH using a convex hull fitting approach and reported a RMSE of 0.009 m. Tree height estimates in the earlier days of terrestrial lidar reported large errors (RMSE 1.4 to 4.4 m) (van Leeuwen & Nieuwenhuis, 2010). Calders, Newnham et al. (2015) have shown that tree height estimates from TLS data captured with the RIEGL VZ-400 agreed closely (RMSE 0.55 m) with destructive harvest measurements, and showed closer agreement and less bias than traditional height measurements (RMSE 1.28 m).

The direct assessment of volumes through QSM reconstruction of tree point clouds from TLS allows for the calculation of AGB using wood density values. Hackenberg et al. (2015) developed a slightly different approach to QSM reconstruction compared to Raumonon et al. (2013), but found similar results when comparing TLS derived AGB estimates through cylinder fitting against destructively harvested measures, with prediction errors ranging from 2.75% to 7.30%. The AGB of the single trees used in both studies was relatively small (Hackenberg et al. (2015) < 0.7 t, Calders, Newnham et al. (2015) < 3.4 t) compared to tropical trees, which can exceed an AGB of

75 t (Chave et al., 2014). Applying these methods in more challenging and complex tropical biomes with larger trees showed similar results (Gonzalez de Tanago et al., 2018; Momo Takoudjou et al., 2018). The modelling error for QSMs is generally quantified by running multiple iterations of the same input QSM parameters. This generally results in small variations in the QSM due to different starting seeds for modelling. Momo Takoudjou et al. (2018) highlighted the importance of manual supervision and correction of the QSMs or the modelling input parameters. Smaller branches are generally not resolved in sufficient detail and will be modelled with higher uncertainty. This is especially true for smaller branches higher in the canopy due to the limitations of TLS instruments. Irregular shaped stems (e.g. due to the presence of buttresses) require mesh-fitting instead of cylinder fitting for these Chapters.

The conversion of tree point clouds to QSMs (see Section 2.3.3.1) requires leaf-off point clouds. Most QSM modelling approaches fit cylinders and presence of leaves would significantly overestimate volume and AGB (Calders, Newnham, et al., 2015). Typical approaches to leaf/wood separation include the inclusion of instrument-specific or intensity-driven methods, or using the geometric properties of the leaf-on point cloud (Boni Vicari et al., 2019; Krishna Moorthy et al., 2019), or a combination of these (Disney et al., 2018).

The use of wood density values that are representative of the whole tree is critical in biomass estimation from tree volume data. Global wood density databases often comprise wood density data sampled from the lower parts of trees (trunk or trunk base), however, wood density is known to vary vertically and radially (Chave et al., 2009). Using destructive data on 15 species in Cameroon, Sagang et al. (2018) showed that a correction was feasible through simple linear models, including a simple descriptor capturing the stem v. crown relative proportions. A larger scale study on 52 species in Central Africa confirms this result (Momo et al., 2020). Another aspect lidar data cannot currently account for is the presence of hollow parts in the trees (Nogueira et al., 2006). In some locations and for some species, this phenomenon can lead to systematic error. Technical solutions, e.g. using the propagation or sonic or radar waves in the trunk are under study.

Trees moving due to wind have a negative effect on the data quality of all 3D sampling methods. In the most obvious case, the tree crowns are in different positions during different scans, e.g. for different lidar campaigns. Additionally, for UAV-LS campaigns commonly using slow vehicles and for TLS campaigns moving trees can cause a spread of points related to the differing tree crown/upper stem positions during the scan. Ultimately, wind might have a different impact for different campaigns. UAV-SfM based data particularly suffers from the movement of objects during data acquisition, as this method relies on the recognition of the same objects in various images, assuming that these objects do not move. In general, the repeatability of all methods increases with decreasing wind speed. Ideally, measurement campaigns should be operated at calm conditions. As TLS and UAV-LS technologies evolve, scanning speed increases significantly (possibly to reach instantaneous scans with single photon lidar technology), but the time taken to move the scanner around to multiply positions will remain commensurate with tree swaying, as is the case in SfM approaches.

### 2.3.4 Recommendations for validation

Calibration and validation of remote sensing data using 3D data from TLS and UAV platforms can be done through two different pathways: (1) a direct assessment of the volume of all the trees in a plot (and conversion to AGB); or (2) the development of local (nondestructive) allometric models based on a representative sample of trees.

The current state-of-the-art has demonstrated that TLS QSMs can be used as a replacement for destructive harvesting (Calders, Newnham, et al., 2015; Gonzalez de Tanago et al., 2018; Momo Takoudjou et al., 2018; Stovall & Shugart, 2018). TLS sampling methods can be leveraged for accurate AGB land product calibration and validation with full plot-level geometric reconstruction and targeted tree-level acquisitions for allometric equation development. Plot-level reconstruction requires all trees in a plot to be modeled and is most feasible in less occluded forests, e.g. deciduous forests in leaf-off conditions. Tropical forests pose a major challenge due to high occlusion and large plot-size requirements, but TLS can clearly benefit the assessment and validation in high AGB density forests. Targeted tree-level geometric modeling can improve allometric models by sampling a full range of tree sizes and increasing the sample size for allometric model training. A greater immediate benefit from TLS is thus likely in the improvement of local and regional allometric models, as these can be built and amended from numerous tree- or plot-level TLS acquisitions and applied to existing forest plots.

Stovall & Shugart (2018) assessed both approaches for a temperate forest and outlined a framework for reducing uncertainty in biomass product calibration and validation. The key finding was clear TLS-driven improvements in AGB uncertainty by reducing allometric error and providing a more direct estimate of standing AGB. Stovall and Shugart (2018) tested the TLS approaches against traditional allometric methods and showed a reduction in plot-level uncertainty from 81.1 to 62.4 Mg ha<sup>-1</sup> (29.5% to 20.4%) RMSE for lidar-based mapping products. An adaptive approach using both plot-level reconstructions and TLS allometry **is recommended** to maximize the potential benefits from TLS.

Initial work on estimating volume from dense UAV-LS data is promising and further development of UAV-LS methods can bridge the gap between airborne and terrestrial lidar. Both pathways require high quality data that represent the full structure of the tree. This might not be possible with UAV-SfM, but these data are still useful for upscaling at a relatively small cost.

### 2.3.5 Summary and current knowledge gaps

Studies estimating AGB from TLS are encouraging as TLS does not only support near-direct estimates of AGB (via volume, and wood density), but can also improve current allometric models. Destructively harvested reference measures of volume and AGB are expensive and time-consuming and hence tend to be very limited both in terms of the number of trees and their size (very few large trees are sampled in this way). TLS data have the potential to provide similar volume information at a fraction of the cost, that are less biased in terms of tree size distributions. This is likely to reduce the uncertainty of the resulting reference AGB estimates compared with the use of existing generalized allometric models that underpin all current field-

based and satellite-derived AGB estimates. Current geometric modeling methods provide clear, detailed and accurate characterizations of structure at an individual tree level, but more development is required to automate algorithms to provide efficient plot level AGB estimates. In dense tropical forests, individual tree and leaf vs. wood segmentation also remain challenging to automate.

One of the current limitations is that only the parts of the trees that are surveyed in the data will be modelled. Data gaps in the tree point clouds can be due to occlusion of other plant components, sensor characteristics, but also due to platform choice. Future research is needed to see if UAV derived AGB estimates are as accurate as TLS-based estimates. Fusion of UAV and terrestrial lidar data can potentially be an important tool for the 3D mapping of forests at plot to landscape levels, which will be key for the reduction of large scale measurement and scaling uncertainties in AGB and carbon estimates.

# Chapter 3: Linking Reference Plots to Satellite Data

## 3.1 Spatio-Temporal Mismatches During Calibration/Validation Procedures

Maxime Réjou-Méchain, Michael A. Wulder, Valerio Avitabile, Laura Duncanson, Nicolas Barbier

### 3.1.1 Introduction

Remote sensing (RS) studies aiming at mapping forest biomass typically rely on ground-based estimates of biomass for calibration or validation. Whatever the biophysical variable of interest, the basic assumption is that the area measured on the ground at each sample point can be spatially and temporally matched with the same area as viewed via remote sensing. The magnitude of this approximation, and of the resulting spatial or temporal mismatch between ground and RS data, can be impacted by several factors, offering a source of uncertainty and/or systematic error in the final biomass map (Frazer et al., 2011; Gobakken & Næsset, 2008; Mascaro et al., 2011; Mitchard et al., 2014; Réjou-Méchain et al., 2014). A better understanding of these sources of ground and remotely sensed data mismatches provides an opportunity for improvement for RS-based biomass approaches.

Four main sources of discrepancy have been reported in the literature: i) mismatch between field plot and pixel sizes and shapes (e.g. Réjou-Méchain et al., 2014); ii) spatial coregistration errors (e.g. Gobakken & Næsset, 2009); iii) lack of agreement between the forest components measured from the field (trunks) and from airborne/satellite signals (mostly crowns) (e.g. Mascaro et al., 2011) and iv) temporal difference between RS and field measurements (e.g. Avitabile & Camia, 2018). In this chapter, we review and describe these sources of mismatch and report new results from simulations to offer insights on how to understand or mitigate known issues. We finally discuss the implications of these errors for future satellite-based missions and provide practical recommendations for future work. For the purposes of forest biomass mapping in this chapter, we refer to coarse resolution as  $\geq 500$  m, medium resolution as 30-500 m, and high resolution as  $\leq 30$  m.

### 3.1.2 Mismatch between field plot and pixel sizes

An obvious, though common, mismatch source is the use of field plots smaller than RS pixels. This represents a typical problem for large area biomass mapping using RS data sources with pixel sizes  $\geq 500$  m while field plots size often ranges from 0.04 to 1 ha, hence representing at best a 4% spatial sample of the larger pixels (e.g. Baccini et al., 2012; Saatchi, Harris, et al., 2011). Using

large forest plots (8-50 ha in area), Réjou-Méchain et al. (2014) quantified the error due to such mismatches using plots of different sizes nested in a 4 ha RS footprint size (i.e. a 200 by 200 m pixel). They showed that this source of sampling mismatch can lead to errors of more than 30% on average, when using combinations of field plot and footprint sizes classically reported in the RS literature. Note that this error estimate was likely underestimated because the large plots from which the analyses were done contained contiguous mature forest while large pixels often include a mosaic of forest and non-forest areas. Importantly, even at medium ( $\leq 50$  m) resolution and within a forest context, this sampling error may still be large when smaller field plots are used due to a very high variability of forest biomass at a fine spatial grain (Réjou-Méchain et al., 2014).

Research using coarse to medium resolution RS products to extrapolate biomass measurements thus have to minimize this mismatch to reduce subsequent statistical errors that may propagate as a bias in the final map. **It is therefore recommended** to use a large field sampling area in general and, when possible, the calibration and validation of RS products using reference biomass values measured at the same spatial grain with that of the remotely sensed data source. When not possible, e.g. with coarse resolution products, several small plots may better capture the mean AGBD of a large pixel than a single large plot for a same total sampling area, even if this implies much more intensive field works, due to spatial correlation in AGBD distribution (Réjou-Méchain et al. 2014). More generally, two strategies may be adopted. First, a multi-step calibration approach can be implemented where intermediate high-resolution products, such as lidar, are calibrated from field plots and then used as reference to calibrate coarser-resolution remote sensing data (Asner et al., 2013; Baccini & Asner, 2013; Réjou-Méchain et al., 2019; Xu et al., 2017). More details and our recommendations for using airborne lidar biomass maps for satellite product validation are presented in Section 3.2. The second strategy involves filtering plots that are not representative of larger pixels. This may be done through a screening procedure using higher resolution images and may be implemented to remove plots that are obviously not representative of the pixels. Such screening may tend to primarily filter low biomass plots located in open or fragmented forests, which are less likely to be representative of the larger, heterogeneous pixels. In such cases, to avoid creating a bias in the reference dataset by selecting only high-biomass plots, it is appropriate to further prune it to obtain a subset that also maintains the frequency distribution (i.e., histogram) of the original dataset in terms of number of plots per biomass class (Avitabile & Camia, 2018). Such an approach can be done visually using google images (Avitabile et al., 2016) or automatically using e.g. high resolution imagery (Mermoz et al., 2015) or, more likely, optical satellite derived land cover. More details of this second approach are presented in Chapter 6.

### 3.1.3 Spatial co-registration errors

**BOX 3.1****Satellite navigation basics**

Global navigation satellite systems (GNSS) provide timing and positioning information based on the triangulation of signals sent by visible satellites of all currently available constellations (GPS, Galileo, BeiDou, GLONASS). The signals consist of radio waves at different frequencies in the L band and on the basis of the wave traveling time, receivers on the ground can compute a pseudo-range (comprising error due to clock uncertainty in the receiver). With signals from at least four non-aligned satellites, receivers can solve for XYZ position and clock uncertainty. Low grade receivers only use information contained in the code, while higher-end devices are also able to interpret phase shifts in the carrier waves to attain higher precision levels. Differential GNSS uses fixed ground stations (or networks thereof) to account for errors in pseudo-ranges obtained in a given geographic region at a given time, notably due to ionospheric and tropospheric perturbations of the radio-signal. These corrections can be used directly, real-time kinematic, or a posteriori, post-processed kinematic, to correct the positions acquired with a mobile DGNSS device (rover). Importantly, to achieve precise absolute positioning of the rover, the position of the fixed receiver (base) itself must be known accurately. Increasingly, for tropical regions where base station networks are sparse, alternatives exist such as Trimble RTX subscriptions or relatively cheap and easy to use devices (e.g. Reach RS2).

Spatial co-registration is required to assign a ground-based estimate to a remotely sensed signal. Hence, Global Navigation Satellite System (GNSS, Box 3.1) instruments are generally used to geolocate ground measurements (e.g., GPS, GLONASS, Galileo). GNSS accuracy is known to strongly vary depending primarily on the grade of the receiver, the sampling strategy, the number and positions of the satellites viewed, and on atmospheric, topographic and vegetation conditions (C. E. Johnson & Barton, 2004). For instance, Genova and Barton (2003) deployed two identical GNSS receivers side by side and registered the signal through time. They showed that some errors of up to 5-m were not synchronous, hence due only to the technical limitations of the instruments. GNSS technology was initially developed to be used in open areas, where acquisition conditions are much better than under forest cover. However, the propagation of L-band waves is impacted by the water content in the troposphere and in plant leaves. Thus, several studies have shown that forest canopy strongly disturbs the GNSS signal (foliage can diminish the GPS data logging efficiency by 47%; (Sigrist et al., 1999)), leading to an exponential increase of GNSS errors with canopy closure. Indeed, GNSS antennas are omnidirectional in order to capture satellite signals so that they also receive “polluted” signals that have been reflected by e.g., the ground, the leaves or the trunks. This phenomenon, known as multipathing, is particularly important in dense multi-layered ecosystems such as forests, resulting in significant GPS errors. Using two precise GPS receivers simultaneously located in an open-field and under a forest canopy in the same area, Johnson & Barton (2004) showed that while GPS errors were less than  $\pm 5$  m for ca. 90% of the measurements in the open-field, the GPS errors were larger than  $\pm 5$  m for ca. half of the measurements and larger than  $\pm 10$  m for ca. 20% of the measurements under a forest canopy, with errors in some cases rising to more than 200 m under unfavourable satellite conditions. Topographical position is also expected to significantly influence GNSS accuracy with previous studies showing GPS accuracy was higher in ridge locations than in valleys (e.g. Deckert & Bolstad, 1996). As a consequence, previous work has indicated that accounting for GNSS-based plot location error could improve the root mean square error (RMSE) of AGBD in the order of 5-18% (Jung et al., 2013).

To determine whether technology has advanced since those studies, we repeated an experiment in a dense tropical forest in Gabon with a recent high grade instrument, likely to have better performance than most devices currently used in forest inventories (see full methodology at **Appendix B**). Our results show an exponential decrease in position bias with the number of averaged GNSS points used (Fig. 3.1). The bias associated with a single point is of 5 m on average but can reach more than 70 m (confidence interval based on the 97.5<sup>th</sup> percentile). Bias decreases markedly when estimating the plot position using measurements from multiple locations, as the upper confidence interval goes under 5 m with 20 points and below 3 m for 50 GNSS points, confirming that georeferencing a ground forest plot requires dozens of measurements at different places or times (Sigrist et al., 1999). An important aspect to consider when taking multiple points is to maximise the difference between the conditions of acquisition, i.e., accounting for the local forest structure and for the position and number of satellites available. **It is therefore not recommended** to average positions over a few seconds or minutes in the same place when under dense canopies; minimum lags of 30 minutes between acquisitions are preferable. While differential GNSS corrections may provide highly accurate measurements in open areas (C. E. Johnson & Barton, 2004) and is often thought as valuable in forest environment (e.g. Chen et al., 2012), it did not bring any improvement in the forested study site, probably because phase shift information is too sensitive to vegetation cover to be used and the fixed station can only account for atmospheric effects, and not for the (larger) impact of the vegetation cover itself.

**Figure 3.1 Geopositioning errors in a tropical dense forest from Gabon.** Higher envelope of the confidence interval of plot positioning error (97.5<sup>th</sup> percentile of obtained position bias) in function of the number of GNSS points used, and the effect of differential correction. Black: no differential correction, Red: differential correction.

These results have important implications as in most cases, forestry plots are geolocated using recreational GNSS instruments and a single GNSS measurement at the plot center, in case of rounded plots, or at one of the plot corners, leading to a potential mismatch between ground and remotely sensed data (e.g. Fig. S3 in Réjou-Méchain et al., 2015) and possible errors in RS models (Frazer et al., 2011). Note that accurately georeferencing circular plots is more

challenging than for square plots as a single point (the center) can be measured and circular plots that are often smaller than square plots are generally rapidly established, offering less possibility to take different GNSS measurements in time. Practical recommendations for georeferencing a plot are given in Box 3.2.

### **BOX 3.2**

#### **Georeferencing a field plot in practice**

GNSS devices are not precise enough to initially set up a plot on the field, hence, field plots should be ideally delineated with a theodolite or with a precise compass on the field for angles and with a laser or decameter (if the terrain is flat) for distances. Note that a magnetic declination exists in many areas (systematic difference between magnetic and geographic north) and should be accounted for during plot establishment and in the subsequent steps. When the plot is established, the georeferencing should start with a minimum of 15 GNSS points taken at different times (> 30 minutes between measurements) in the plot center for circular plots or at the four corners for square plots. If not possible, GNSS points can be taken consecutively in different places where the relative coordinates of the plots are precisely known (which is challenging for circular plots). Mounting the GNSS field antenna on telescopic rods may improve data acquisition conditions but the gain in accuracy is expected to be very low in tall canopy forests. Finally rigid transforms should be done to convert the relative coordinates into absolute geographical coordinates. This step can be done in the R statistical software with the `correctCoordGPS` function of the BIOMASS package (Réjou-Méchain et al., 2017).

Under dense canopies where collection of highly accurate geolocation information is particularly challenging, acquisition of UAV and/or airborne lidar can be used to correct for poor plot registration because their mounted GNSS sensors are not obstructed by the forest cover and thus provide good positional accuracy. These remote sensing data can be used in conjunction with stem mapped tree height measurements in the field to manually adjust plot corners (e.g. Labriere et al., 2018; Réjou-Méchain et al., 2015) or to automatically co-register forest inventory and lidar data (Dorigo et al., 2010). Matching between terrestrial and airborne lidar acquisitions, when both can be available, is possibly the best case scenario (see Chapter 2) as common canopy features are readily recognisable in both sources. A more traditional approach is to use surveying instruments such as theodolites to traverse from open areas, where good DGNS positions can be obtained, to the plot. This however requires large openings in the plot vicinity, or an access to the canopy.

Finally, if ground-based data are inaccurately geolocated, remote sensing products using these data for training also are affected. Additionally, satellite product geolocation or geometric accuracy is expected to vary by platform and instrument. However, different studies use different accuracy metrics making any comparison challenging. As a few examples, ALOS-2 Phased Array type L-band Synthetic Aperture Radar (PALSAR)-2 data are expected to have a geolocation error of 6.2 m on average (Motohka et al., 2018), Landsat-8 data is predicted to have a geometric error of 12.6 m (90% circular error; Storey et al., 2014), the GEDI requirement is to have geolocation error of less than 10 m on average (Dubayah et al., 2020) and the NISAR calibration and validation plan (VO.9 JPL D-80829 5/14/2018) states geolocation accuracy of NISAR is expected to be better than 10 m. Thus, the spatial uncertainty associated with remote sensing data may easily be of the same order or higher than that of ground measurements making any coregistration of small plots and individual pixels highly uncertain.

### 3.1.4 Discrepancies between forest components estimated from field and remote sensing approaches

An important source of spatial mismatch is that forest biomass is differently “seen” by RS and field measurements. While field measurements are generally “trunk-based”, considering a tree only if at least half the trunk base section is within the plot, RS sensors measure forests from an area- or volume-based perspective, considering only the plant material having a ground projection within the plot. Mascaro et al. (2011) showed that this representation mismatch leads to strong edge effects due to the bisection of tree crowns in lidar data, which then generates large errors in lidar-AGB models. Naturally, the impact of these edge effects on the global mismatch between field and RS measurements decreases with the spatial grain at which RS models are calibrated/validated (Mascaro et al., 2011). Given that this error is tightly linked to tree crown size, it also strongly depends on the forest type (e.g. needle leaf versus broadleaf forests) and is expected to increase with the forest successional status (Frazer et al., 2011).

**Figure 3.2** Illustration of the mismatch generated by an incidence angle ( $\alpha$ ) of ca.  $30^\circ$  and a field plot size of ca. 25 m. The hashed polygon illustrates the match existing between the forest volume measured by both the satellite sensor (in orange) and from the field (black). In this example, the large heterogeneity of the forest at the plot scale would result in significantly different biomass estimates from the satellite and ground measurement.

Another “representation” mismatch is that satellite instruments do not necessarily measure forests at nadir, i.e. from a purely vertical perspective. In particular, radar sensors are often used with an incidence angle typically  $> 30^\circ$  in order to minimize the contribution of soil backscatter (Robinson et al., 2013). For instance, Saatchi et al. (2011) recommended incidence angles of  $30^\circ$ – $40^\circ$  for estimating AGBD in temperate forests using L-band radar. With such incidence angles, we may expect a relatively high mismatch between the volume of the trees measured from the ground and the volume intercepted by the satellite sensor, especially for small plots (Fig. 3.2) or in topographically complex areas (Villard & Le Toan, 2015). Because this effect has been rarely quantified, we conducted simulations to quantify the effect of incidence angle on the spatial mismatch between ground and satellite-based measurements at different spatial scales, in

addition to geolocation errors (see full methodology at **Appendix C**). The results show that an incidence angle of  $30^\circ$  leads to a large mismatch between canopy volumes measured from the ground and from this particular RS sensor for small plot sizes, with an error of more than 50% with 20-m plots (Fig. 3.3). When geolocation errors are jointly simulated the error becomes larger, e.g. with an incidence angle of ca.  $30^\circ$  and a geolocation error of 15 m, the mean error was larger than 70%, 35% and 20% for plot size of 20, 50 and 100 m respectively. This indicates that whenever a signal is intercepted at a marked incidence angle, large field plots are needed for calibration and validation. However, if the forest structure is spatially homogeneous, the forests surrounding the plot are structurally similar to that inside the plot, and therefore errors associated with incidence angles are partly offset, with RMSE values peaking at only 30%. This also explains noisier error trends on the bottom row of Figure 3.3 due to a random contribution of trees located outside the plot.

There are two solutions to minimize uncertainties due to viewing geometry. First, the spatial resolution at which calibration/validation is done should be large enough to maximize the overlap between RS and field observations. Second, terrestrial lidar point clouds may be used instead of traditional trunk-based measurements so that field data may match RS observations while explicitly accounting for RS acquisition parameters such as the incidence angle - if using synthetic aperture radar (SAR) data.

**Figure 3.3 Joint effect of plot size (Plot), sensor angle incidence (Tilt) and geolocation error (Shift) on difference in total crown volume estimated by an active remote sensor and the same volume as generally measured from the ground with trunk-based measurements.** The sensor's footprint is identical to the plot size. The top row only considers the volumes of the trees measured within the plot and the bottom row also considers the volumes of the trees surrounding the plot, allowing for error compensation.

### 3.1.5 Temporal difference between RS and field measurements

A common problem during RS calibration/validation is the temporal difference between RS and field measurements which are difficult to acquire simultaneously, particularly at large spatial scales. For biomass applications, increases in tree mass occur slowly over time, and thus ground measurements can often be used for calibration/validation of RS for a few years after acquisition provided it is a relatively slow growing forest (i.e., not a recovering tropical forest), and there is no major biomass disturbance between the field and RS acquisitions. However, growth, turnover and disturbance rates vary through space and time, and cannot always be detected by optical sensors. The impact of this temporal difference is difficult to quantify due to the strong stochastic component in natural forest temporal dynamics. Chambers et al. (2013) showed, however, that the error associated with temporal difference between measurements tends to decrease with plot sizes in mature forests as the AGB gains and losses at large scales average out. Thus, as the spatial resolution at which calibration/validation is performed gets coarser, the error due to temporal mismatches tends to be smaller. However, even large plots are subject to large scale ecological disturbances such as hurricanes (Espírito-Santo et al., 2014) or to large scale mortality events during drought years (Feldpausch et al., 2016; O. L. Phillips et al., 2009). Thus, whenever a temporal difference exists between RS and field measurements, RS time series, such as Landsat (M. C. Hansen et al., 2013; Kennedy et al., 2010) or MODIS (Justice et al., 2002), may be used to discard any area that may have suffered from major disturbances, such as hurricanes or fires, during the intervening time. With the recent increase in the number of small satellite constellations designed to observe Earth (Boshuizen et al., 2014), high magnitude forest disturbances (e.g. wildfire, harvesting) may be monitored with a high temporal (within a month) and spatial (e.g. 5 m) resolution (Finer et al., 2018). Note also that whenever young, high productivity secondary forest areas are considered, growth is difficult to detect from time series data such as from passive optical satellite data that are generally insensitive to slow increases in height beyond some saturation threshold. In this case, estimated growth rates may be used to correct and temporally align field and remote sensing measurements (Avitabile & Camia, 2018).

### 3.1.6 Discussion and recommendations

In this chapter, we have shown that several sources of spatial or temporal mismatch may occur during the calibration and validation steps potentially leading to estimation errors. A common feature of these error sources is that they all decrease with increasing plot size. Indeed, the spatial overlap between field and RS observations increases with plot size in presence of mismatch between field plot and pixel sizes (Réjou-Méchain et al., 2014), coregistration errors (Frazer et al., 2011), crown-bisection effects (Mascaró et al., 2011) or incidence angles. Further, temporal differences are also expected to be better controlled with large field plots. Thus, the size of the plots and the spatial scale at which the RS product is calibrated or validated should be large enough (typically 1 ha in tropical forests) to minimize these errors.

As presented in this chapter, the minimum spatial scale that should be adopted during a calibration/validation approach is context-dependent, varying with sensor resolution, incidence angle and forest structure. For instance, the future BIOMASS mission, a P-band radar mission to be launched in 2022, will have a medium AGB product resolution of 200x200 m<sup>2</sup> with an incidence angle of 23 to 32° thus potentially generating large mismatch errors with small calibration/validation plots, especially in heterogeneous mature tropical forests. In such a case, the calibration/validation strategy should rely on either large plots or use a two step calibration strategy using intermediate high-resolution products, such as lidar (Réjou-Méchain et al., 2019). By contrast, the future GEDI mission will acquire data on a near-nadir mode and at a 25 m-resolution suggesting that smaller calibration plots may be used. One of the most important challenges for the GEDI mission will be the co-registration accuracy and the edge effects that may at that scale dominate all other errors.

In summary, **it is recommended** that calibration and validation are conducted at the resolution of the satellite product or sensor, and large well-georeferenced (see Box 3.2) field plots (1 ha where possible, and at least 0.25 ha under dense canopies) should be used with subplot information enabling multiple satellite products to be compared to a single plot. Smaller plots are suitable for areas with relatively sparse canopies and typically lower biomass densities (<100 Mg/ha), where geolocation accuracies are higher. Finally, where possible **it is recommended** to acquire TLS data when comparing field plots to RS data acquired with high incidence angles.

## 3.2 Linking Field Plots to Spaceborne Data using Airborne lidar

John Armston, Laura Duncanson, Sassan Saatchi, James Kellner

### 3.2.1 Background

Airborne lidar, or Airborne Laser Scanning (ALS), has been demonstrated as a technology to near-directly measure forest canopy height, cover and vertical structure and can produce high-resolution (sub-meter) map products (Dubayah et al., 2000; Wulder et al., 2012). ALS measures tree height using laser-based ranging from above and can resolve distance as accurately, if not better, than techniques used in the field (Asner et al., 2010). ALS are therefore considered the most reliable remote sensing observations to link with ground-based tree measurements and estimate aboveground forest biomass. The precision of ALS systems and their ability to rapidly map a large area provides us with an alternative to direct measurements of forest structure. These data can help to scale up field measurements to landscape scales (> 1 km<sup>2</sup>) and provide an intermediate step between field plot measurements and EO data.

Airborne lidar, in many ways, is the gold standard reference dataset for training and validation of forest structure and biomass satellite products from EO. While for many forest applications ALS acquisition and processing protocols are operational, important data acquisition, processing, AGBD modeling and mapping decisions can impact the accuracy of ALS AGBD reference maps. In this section, we summarize the general approaches to using ALS for EO biomass map product

validation, including decisions on data acquisition, processing, AGBD modeling, generation of AGBD maps, and comparison to EO map products.

### **3.2.1.1 Development of the multi-stage approach**

We generally treat ALS data as more reliable for relating to biomass than spaceborne lidar data due to several sources of measurement and sampling uncertainty inherent in ICESat/GLAS, ICESat-2 and GEDI observations. A frequently used approach for wide area biomass mapping uses ALS data as an intermediary to link field plots and satellite data (e.g. Nelson et al., 2017). Generally this involves clipping airborne lidar to match the spatial extent of field plots, generate some empirical model to estimate field AGBD estimates from ALS, application of that model to the full airborne lidar dataset, and finally building some empirical relationship between airborne lidar estimated AGBD, and EO data. There are several advantages to this three-tiered approach over linking field plots directly to EO data. First, it allows the use of field plots that are not of the same size and/or shape as EO measurements (e.g. for circular or near circular spaceborne lidar from GLAS or GEDI, or large pixels from SAR sensors or MODIS, as in Boudreau et al., 2008). Secondly, it allows training satellite models with a larger sample size from the ALS than is often available from the field data (e.g. Neigh et al., 2013). And finally, if the relationships between airborne estimates and satellite data are consistent through space and time, time series satellite data may be used to map changes in AGBD through time (e.g. Margolis et al., 2015b). This approach can also be extended to satellite biomass map validation through the generation of ALS reference maps that enable a richer sample of structure across environmental gradients (e.g. Duncanson et al., 2020).

### **3.2.1.2 Reference sites and large area sampling**

There are a wide range of ALS sampling approaches adopted in the literature, which reflects the diversity of application but also resources available to users. In general, two types of approaches to large area sampling exist: (i) local wall-to-wall ALS over a reference site or set of reference sites; and (ii) large area acquisitions either as transects or through the use of a high altitude large footprint waveform system such as the NASA Land, Vegetation, and Ice Sensor (LVIS). There are advantages and disadvantages to each approach. In the former, detailed structural measurements are available to produce local AGBD maps, but with limited geographic coverage. Conversely, the latter approach yields broader spatial coverage but often with either less spatial detail, or transect samples that may be more difficult to link with field plots and/or satellite datasets. Both approaches are useful for EO biomass product calibration and validation, but we focus our recommendations on smaller area high point density wall-to-wall mapping coincident with permanent field plots. A number of existing lidar campaigns have been conducted following both approaches, with some examples provided in Table 3.1.

**Table 3.1 Examples of local:regional vs. transect lidar sampling acquisitions.** This is by no means an exhaustive list as hundreds of campaigns have been conducted, but highlights the diversity of ALS campaigns.

Collection	Sampling approach	Instrument	Reference
TERN (Australia)	Wall-to-wall	RIEGL LMS Q560	Cleverly et al. (2019)
AfriSAR (Gabon)	Wall-to-wall and transects	NASA LVIS Facility	Fatoyinbo et al. (in review)
Arctic Boreal Vulnerability Experiment (ABOVE)	Transects	NASA LVIS Facility	Miller et al. (2019)
BIOMASS reference data (French Guiana and Gabon)	Wall-to-wall	RIEGL LMS Q560	Labriere et al. (2018)
Trans-Canada	Transects	Optech ALTM	Wulder et al. (2012) Hopkinson et al. (2016)
La Selva, Costa Rica	Wall-to-wall	NASA LVIS	Dubayah et al. (2010)
Norwegian Inventory	Transects	Portable Airborne Laser System (PALS)	Gobakken et al. (2012)
Alaska Inventory	Transects	NASA's GLiHT	Babcock et al. (2018)
NEON sites	Wall-to-wall	Optech Gemini	Kampe et al. (2010)
Sonoma County	Wall-to-wall	Leica ALS70-HP	Dubayah et al. (2017)

We fully appreciate the value of wider area transect samples (as outlined in Table 3.2), particularly for multi-tiered biomass model training and regional to national validation - these fill an important niche for national inventories and calibration and validation of EO forest structure maps. However, we hope to move toward a global set of AGBD reference sites with both consistent field and ALS acquisitions, and the design of transect-based acquisitions by nature will vary by the design selected to fulfill the goals of the associated project. As there is no 'one size fits all' transect sampling approach for global product validation, **it is recommended** to adopt local to regional wall-to-wall airborne lidar samples over permanent sampling plots.

**Table 3.2 Advantages and challenges of large area lidar sampling approaches using ALS.**

Approach	Advantages	Challenges
Local wall-to-wall	<ul style="list-style-type: none"> <li>● Ensures complete detailed coverage over field plots</li> <li>● Can be collected with UAV-LS</li> <li>● Higher point density from overlapping swaths</li> <li>● Can be used to build a global network coincident with in situ plot monitoring networks</li> <li>● Data processing and management packages can be consistently applied across many regions to produce local ALS AGBD maps trained with field data</li> </ul>	<ul style="list-style-type: none"> <li>● Requires consistent methodology to resolve differences between instruments and surveys</li> <li>● Low intensity sampling across environmental gradients</li> </ul>
Transects	<ul style="list-style-type: none"> <li>● Wider area coverage</li> <li>● Cost-effective as can be collected in-transit</li> <li>● Flexibility to design sampling strategy (e.g. design-based or model-based uncertainty frameworks enabled)</li> <li>● Flight lines can be designed to sample many far ranging field plots</li> <li>● Sampling design can be flexibly designed based on forest type, extent, and environmental gradients</li> </ul>	<ul style="list-style-type: none"> <li>● Typically lower point densities / precision associated with higher altitude acquisitions</li> <li>● Most susceptible to changing weather patterns (potential loss of quality data over some plots)</li> <li>● Uncertainty estimation more complicated as field plots will typically not be representative of all forest types sampled</li> </ul>

### 3.2.2 Data acquisition protocols

#### 3.2.2.1 Instrument specifications and limitations

There are three classes of lidar instruments commonly used in ALS systems:

1. **Discrete return lidar** - these systems use analogue detectors to record discrete, time-stamped trigger pulses from the received waveform in real time
2. **Waveform lidar** - these systems digitize the transmitted and received waveforms at a high frequency and records the energy returned over equal time intervals
3. **Photon counting lidar** - equipped with more sensitive sensors, these systems detect the presence of returned photons rather than waveforms

The vast majority of research and almost all operational applications for estimation of biomass from ALS have used small footprint discrete return lidar systems operating in the near infrared wavelength (see Table 3.3). However, small footprint waveform lidar instruments are now commercially accessible and several other sensor types are available and of use for biomass

product calibration and validation, including research instruments such as NASA's LVIS and photon counting instruments such as the Multiple Altimeter Beam Experimental Lidar (MABEL).

For the purposes of AGBD product validation **it is not recommended** to use airborne photon counting instruments. Method development for photon counting lidar is advancing with the recent availability of ICESat-2 data (e.g. Narine et al., 2019), however airborne instruments are not widely accessible and further research is needed to use these for routine generation and ALS reference forest structure and biomass maps (Swatantran et al., 2016). Both full waveform and discrete return instruments are well established, and often used operationally, for large area mapping (Asner et al., 2010; Wulder et al., 2012). It is important to acknowledge UAV-LS, which has emerged as a new datastream that can collect high quality, repeatable forest structure measurements that fill a niche between ALS and TLS for biomass calibration and validation activities (see Chapter 2.3 for further details).

### Discrete return lidar

- In the last decade discrete return instruments have matured considerably, with reduced dead-times, increased number of pulses, and a proliferation of software to process point clouds. **It is recommended** to use instruments with  $\geq 4$  returns per pulse to ensure vertical structure is captured and avoid older instruments with only first and last returns.
- Has underpinned the development of operational forest inventory programs and algorithms for tree level attributes such as crown shape, height and biomass have almost been solely developed on these data (Holmgren & Persson, 2004; Vauhkonen et al., 2009).
- Rapid advances in discrete return lidar technology and the large number of different instruments available at any one time have resulted in disparate instrument characteristics. The impact of differences in analogue return detection methods, laser power, etc. on forest structure estimates are difficult to resolve (Disney et al., 2010; Næsset, 2009).

### Waveform lidar

- Processing of waveforms to discrete returns is done in post-processing. This enables additional points and attributes of these points (e.g. apparent reflectance) to be derived, providing additional information on canopy properties. Benefits of small footprint waveform lidar for biomass estimation is yet to be shown, however national programs such as the Terrestrial Ecosystem Research Network (TERN) and the US National Ecosystem Observation Network (NEON) are making waveform datasets available for applications.
- Enables more direct retrieval of canopy cover and the vertical foliage profile that are less sensitive to survey configuration differences than discrete return lidar (Armston et al., 2013; Chen, Vaglio Laurin, et al., 2015).
- Large footprint waveform lidar has a long history (> 20 years) of method development for canopy structure and biomass estimation, which has:
  - demonstrated vertical canopy structure can be rapidly and efficiently mapped over large areas when flown at higher altitude with larger footprint size (e.g. NASA's LVIS)

- underpinned the development of the NASA GEDI mission (Dubayah et al., 2010, 2020).
- exhibits greater uncertainty in height estimation on steep slopes because the ground and canopy signals blend, with this uncertainty increases with increasing footprint size (Hyde et al., 2005).

**Table 3.3 Examples of ALS instruments used in the estimation of forest structure and AGBD.** This list is non-exhaustive and new commercial instruments are often released by a number of manufacturers.

Instrument	Instrument type	Number of returns	Wavelength [nm]	Maximum Flying Height [m AGL]	Maximum laser pulse repetition rate [kHz]	Beam Divergence [mrad]	Max FOV [deg]	References
NASA Land, Vegetation & Ice Sensor (LVIS) Facility	Large footprint waveform	N/A	1064	20000	4	0.75 to 3	12	Fatoyinbo et al. (in review) Blair et al. (1999)
Leica ALS50-II	Discrete return	4	1064	6000	150	0.22	75	Hudak et al. (2020)
Leica ALS70-HP	Discrete return / waveform optional	unlimited	1064	3500	500	0.22	75	Duncanson et al. (2020)
Optech Orion-M	Discrete return / waveform optional	4	1064	5000	500	0.25	50	Longo et al. (2016)
Optech Gemini	Discrete return / waveform optional	4	1064	4000	167	0.25 or 0.8	50	Goulden and Scholl (2019)

RIEGL LMS-Q560	Waveform	unlimited	1550	1200	200	0.5	60	Labrière et al. (2018)
RIEGL LMS-Q680i	Waveform	unlimited	1550	5000	400	0.5	60	Armston et al. (2013)

### 3.2.2.2 Survey requirements

ALS instruments vary in their laser wavelength, pulse repetition frequency (PRF), pulse length, pulse shape, signal triggering mechanism, detector sensitivity, beam divergence, vertical discrimination distance, and scan pattern. Surveys vary in their flying height above ground, flying speed, maximum off-nadir scan angle, scan rate and swath overlap. Changes in ALS discrete

return instrument and survey characteristics can cause differences in canopy height and cover estimates independent of forest structure and that are difficult to quantify directly (A. Fisher et al., 2020; Næsset, 2009).

Given the importance of accurate digital elevation models (DEM's) for modeling canopy height, particularly in tropical forests, their accuracy requirements are directly relevant for ALS biomass map generation. For example, the US Geological Survey (USGS) Lidar Base Specification (Heidemann, 2018) outlines quality levels that define minimum acceptable ALS acquisition parameters to ensure consistency between independent ALS acquisitions for the USGS 3D Elevation Program (3DEP) Program. Generation of accurate ALS biomass maps across multiple independent ALS acquisitions that follow such guidelines has been achieved (Hudak et al., 2020).

For forest applications a minimum density of 8 pulses/m<sup>2</sup> and non-vegetated vertical accuracy of  $\leq 0.196$  m (95% confidence interval) **are recommended** (Heidemann, 2018). This is greater than the often recommended density of  $\geq 4$  points/m<sup>2</sup> for consistent measurements of forest canopy height and ground elevation in tropical rainforests (Leitold et al., 2015), which National Science Foundation (NSF) NEON ALS acquisitions also use (Goulden & Scholl, 2019). Hancock et al. (2019) recommended  $\geq 2$  points/m<sup>2</sup> for simulation of GEDI waveforms, with some dependency on ALS instrument type. Individual instrument and survey properties (see Table 3.3) are related to each other so it is difficult to isolate their impact, however ultimately their combined effect on individual laser pulse energy per unit area can lead to errors in canopy height and cover estimation (Armston et al., 2013; Næsset, 2009).

Within constraints of minimum pulse density and areal coverage requirements, **it is recommended** to use commercial survey and instrument configurations that maximize individual laser pulse measurement quality rather than even higher pulse density. Ideally, beam divergence, flight altitude, and pulse repetition rates are set to ensure footprint sizes  $< 30$  cm and maintain sensitivity to canopy foliage. Also important is to ensure the maximum off-nadir scan angle is  $< 15^\circ$  (Goodwin et al., 2007), and set the swath overlap of 50% to ensure creation of a coregistered flight lines, even sampling density, and minimisation of off-nadir scan angle. Existing protocols developed for TERN and NSF NEON outline these requirements in more detail, along with recommendations for quality assurance (QA)/quality control (QC) (Held et al., 2018; Krause & Goulden, 2015).

Wall-to-wall ALS reference sites can be selected in different ecoregions using a minimum area of 3 x 3 km (1000 ha) to capture landscape level variation in topography, forest structure, and composition within the same ecoregion. In addition to minimizing cost and logistics of airborne campaigns, a minimum area of 1000 ha will enable comparison with EO biomass map products from current and upcoming space missions with biomass requirements (NASA GEDI, NASA/ISRO NISAR and ESA BIOMASS). TERN Australia (Cleverly et al., 2019) used 5 x 5 km and NSF NEON used 10 x 10 km (Kampe et al., 2010).

### 3.2.3 Data processing protocols

Data processing protocols are also variable, with providers using different detection thresholds, ground classification algorithms, noise filtering algorithms, and instrument calibration routines. The basic ALS processing workflow starts with basic QA/QC of lidar point clouds, point cloud classification, noise detection and removal. Again, existing QA/QC protocols developed for USGS 3DEP, TERN and NSF NEON outline these requirements in more detail. For the purposes of this protocol, we will not recreate one of the many excellent lidar processing protocols that are available for the community (Held et al., 2018; Krause & Goulden, 2015; Stoker et al., 2016; J. C. White et al., 2013). We will, however, make general recommendations to minimize uncertainties in ALS AGBD maps associated with lidar processing.

Open source as well commercial software for the complete processing chain from waveform processing (e.g. SPDLib; Bunting et al., 2013) to gridding of canopy metrics, including lidR (e.g. Roussel et al., 2018), PyLidar (Armston, Bunting, et al., 2020) and FUSION (McGaughey, 2020) are increasingly available. In the longer term, the development of open source software that is suited to automated processing will ensure genuine transparency in the algorithms and data products generated from airborne lidar over large areas, and enable other researchers to replicate scientific results without incurring significant financial costs or encountering proprietary barriers.

#### 3.2.3.1 Canopy height models

Ground classification is probably the most important consideration for AGBD reference map generation, since canopy height models are required to derive most ALS area and tree level metrics. However, details in processing algorithms (e.g. the selection of noise thresholds, map spatial resolution) can yield important differences in the final ALS metrics. Best practice is to interpolate ground elevation to the location of each point and then assign a height above ground, prior to gridding the data. These data can be clipped directly to field plot extents for ALS biomass model development (see Section 3.2.4.1), which minimizes uncertainty related to collocation of field plots and ALS metrics (see Section 3.1).

The minimum ALS products required for generation of canopy height models, which underpins the area based approach, are the classified (unfiltered) ALS point cloud. The point cloud should contain all valid returns. Lidar points are typically classified as returns from the ground, canopy, or noise. At some sites, classification of buildings and other infrastructure is required. Most LAS processing software (e.g. LAStools) includes tools for classification, although the majority of commercially acquired ALS data will already have a classification assigned. **It is recommended** to use existing protocols for QA/QC of point cloud classifications (Quadros & Keyzers, 2018).

**It is still recommended** to check the classification visually through a point cloud visualization tool to ensure that noise above and below the canopy has been classified correctly, and that even under dense canopies ground classification appears accurate. Occlusion mapping using voxel traversal of laser pulses can identify which parts of the canopy were acquired by different acquisitions (e.g. Kükenbrink et al., 2017). This basic QA/QC will help ensure errors in

classification do not propagate to errors in height and cover metrics, particularly in areas of high biomass or dense cover (e.g., >400 Mg/ha or >90% canopy cover).

Once a high-quality, classified point cloud is available, typically forest structure (height and cover) metrics are calculated by normalizing points to a height above ground binning the returns into a planimetric grid and then generating statistical summaries or applying retrieval algorithms for biophysical parameters such as canopy cover. Decisions related to the selection of interpolation methods for DEM generation may impact the downstream canopy structure metrics and depend on canopy cover, slope, point density, and classification error. A guide for the generation of raster layers from point clouds is provided by NEON (Goulden & Scholl, 2019). This algorithm theoretical basis document (ATBD) outlines the processing steps for the generation of NEON's analysis ready data (ARD) canopy height and DEM layers, among others.

### 3.2.3.2 Tree or area based approach

In contrast to the relatively convergent ALS processing algorithms for areal-based or plot-level forest structure metric calculation, tree and crown extrapolation algorithms vary considerably in their methodology and accuracy. In the past two decades there has been an emergence of research focus of individual tree extraction from airborne lidar datasets (Duncanson et al., 2014; Ferraz, Saatchi, Mallet, & Meyer, 2016; Koch et al., 2006; Popescu et al., 2003; Roberts et al., 2005). The ecological and management applications of individual tree crown information are obvious, and if individual crown information can be routinely and accurately extracted, individual AGB estimates could be made at a landscape scale. Additionally, individual tree based change detection and AGB dynamics could be monitored from multi-date lidar (e.g. Duncanson, Dubayah, et al., 2015; K. Zhao et al., 2018).

Several papers have attempted to estimate individual tree based AGB using these approaches (Bortolot & Wynne, 2005; Dalponte et al., 2016; Duncanson, Dubayah, et al., 2015; Ferraz, Saatchi, Mallet, Jacquemoud, et al., 2016; Popescu, 2007; K. Zhao et al., 2009). This is attractive as it is theoretically scale invariant (AGB is the sum of biomass of individual trees), and there are promising results showing crown width is an important allometric predictor of AGB (Jucker et al., 2017). However, there is a wide range of methods and associated uncertainties for the breadth of algorithms employed to extract individual tree crown information. Algorithm comparison studies (e.g. Aubry-Kientz et al., 2019; Kaartinen et al., 2012) demonstrate that the accuracy of approaches is both algorithm and ecosystem dependent, and challenges remain particularly in multi-layer forests.

Specific comparisons of individual tree and areal based estimates have found that areal-based approaches have higher associated accuracies as well as following more mature established data processing methods (Coomes et al., 2017; Duncanson, Dubayah, et al., 2015). Tree-based approaches are presently most useful for open forests and conifers, and detection of understorey trees is not reliable (Duncanson, Dubayah, et al., 2015). **It is therefore recommended** that area-based approaches are used for the generation of ALS biomass reference maps, but as individual tree methods continue to mature this may be revisited in future.

### 3.2.4 Biomass modeling and mapping

A huge number of studies have modeled AGBD from airborne lidar structure metrics for purposes of local AGBD mapping, forestry and ecological studies (Zolkos et al., 2013). Models for converting lidar measurements of forest height or vertical structure into AGBD have been developed for different forest types globally (Asner & Mascaro, 2014; E. Hansen et al., 2015; Nelson et al., 2017).

When developing a model for producing an ALS biomass map, one must make decisions about how to link the ALS and field plot data to train the model, the geographic specificity of the model (e.g. local to global), the spatial resolution of the model (and product), model specification (selection of model form, predictors, etc.), and how to characterize uncertainty. Here, we briefly summarize these considerations.

#### 3.2.4.1 Linking ALS to in situ reference data

For linking with ALS data and to minimize the impact of spatial and temporal mismatches (see Section 3.1) on ALS biomass modeling, **it is recommended** that field plot data be acquired using:

1. a constant plot size per ALS campaign (e.g. 0.25 ha) to avoid the assumption of scale invariance and for consistency between campaigns
2. fixed area square shaped plots, which are easier to link to the spatial resolution of EO biomass products, and easier to establish and maintain in tropical forests
3. a plot size large enough to:
  - o include a large number of trees (50-100 for forests) so the mean AGBD estimate of the plot from the allometric model has low variance
  - o minimize the impact of edge effects and collocation error (Gonçalves et al., 2017)

Depending on the forest types and size of trees, the plot size selected may vary. For boreal forests dominated by conifers, plots of greater than 0.1 ha may contain enough trees and have accurate ground estimates of biomass. Highest biomass model accuracies have been reported at the 1-ha scale with a model prediction error typically below 15%. Tropical sites with small plots (<0.1 ha) are more challenging with model prediction errors potentially above 40% (Zolkos et al., 2013). For tropical forests, **it is recommended** to collect plot sizes greater than or equal to 0.25 ha where ALS metrics typically represent forest structure at a scale larger than the crown of a large tree.

As stated above, fixed area square shaped plots **are recommended**. Circular plots are often used in temperate ecosystems with lower tree density and AGBD compared to tropical forests, where they can be easier to establish and maintain due to their often smaller size (e.g., 0.1 ha; J. C. White et al., 2013) and line-of-sight to individual trees for stem mapping. Orientation of plots is less important, but may need to be specified if other imaging sensor data are being acquired in

addition to ALS, for example where square plots aligned in the azimuth direction of SAR flight lines can ensure better collocation with individual pixels (see Section 3.1).

For linking with field plot data and to ensure spatial and temporal consistency in ALS biomass reference maps, **it is recommended** that ALS data be acquired:

1. in maximum leaf-on conditions, where deciduous species are present;
2. before field plots where possible, since the ALS data can be used to select field plot locations for representative sampling and avoid redundant field effort;
3. ideally within one year to minimize the impact of change such as understorey recruitment events, tree fall, defoliation from insect damage; and
4. across a sufficiently large area (minimum 3 x 3 km) to capture landscape scale variation in canopy structure and AGBD, and enable development of more generalizable models.

Temporal alignment between field and ALS acquisitions is important for spatial alignment of field and ALS data (Labriere et al., 2018; Chapter 3.1). Change between ALS and field acquisitions can have a large contribution to total model error with one study showing 7-17% error for 3 years misalignment in tropical secondary forest (Gonçalves et al., 2017). Different approaches are available to account for this error. One is to apply growth models to predict AGB stocks at the time of the ALS acquisition (e.g. Gobakken & Næsset, 2008). However uncertainty in growth model results are not easily propagated through model-based inference frameworks used for characterizing uncertainty (Babcock et al., 2016). **It is recommended** that the time difference between the ALS and field plot acquisition is minimized, which will require budgeting for new ground surveys coincident with airborne campaigns.

#### 3.2.4.2 Model specification

ALS biomass model specification requires the selection of model form and predictor variables, and assessment of model performance. While a wide range of approaches have been used for modeling the relationship between AGBD and ALS metrics, ALS biomass models can be generally categorized into two types of approaches:

1. Data-driven selection of ALS metrics using parametric or machine learning algorithms (e.g. Chen et al., 2018; Duncanson et al., 2020; Esteban et al., 2019; Ståhl et al., 2016)
2. Theory-driven algorithms that are constrained by allometric scaling laws using height, cover and to a lesser extent crown diameter (e.g. Asner et al., 2012; Asner & Mascaro, 2014; Coomes et al., 2017)

Following the theory that underpins tree based allometry (see Section 2.2.3), a number of studies have used a generalized non-linear model form that is a function of canopy top height (H), stand basal area (BA), and stand wood density (WD) (Asner & Mascaro, 2014):

$AGBD = a \times H^b \times BA^c \times WD^d$ , where  $a$ ,  $b$ ,  $c$  and  $d$  are parameters (power-law exponents)  
Stand basal area is also not directly observed from the vertical view of ALS instruments. Asner and Mascaro (2014) recommended using regional models that relate canopy height to stand

basal area, however this relationship can decouple (Duncanson, Dubayah, et al., 2015) and other studies in both temperate and tropical forests have found canopy cover x height improves model performance (Coomes et al., 2017; Fatoyinbo et al., in review; Jucker et al., 2018; Ni-Meister et al., 2010). Model performance is higher when using plot based estimates of mean woody density (Fatoyinbo et al., in review), however ALS metrics are poor predictors of mean wood density therefore regional averages must be used (Coomes et al., 2017).

Data-driven approaches typically use multiple linear regression with a combination of ALS height and cover metrics as predictors (e.g. Drake et al., 2002; Duncanson et al., 2020; E. Hansen et al., 2015). Models are linearized by using logarithm or square root transformations of AGBD (and the predictors) to improve the linear relationship between the response and the predictors and to reduce heteroscedasticity in the models. Statistical modeling procedures to select ALS metrics to use as predictors are well documented in the literature, but **the general recommendation is to minimize the number of predictors in the models to avoid overfitting and multicollinearity.** Model performance should be assessed using cross-validation, including cross-validation based on non-random (e.g., geographic) subsets of the data (e.g. Ploton et al., in press).

One ALS metric that is commonly used is MCH. Theoretically, MCH represents the average canopy height within an area and therefore shows strong correlation to basal area, and hence AGBD. It has been shown to be a robust metric to capture biomass variations across the landscape (Asner et al., 2012; Lefsky, 2010; Meyer et al., 2013). The equivalent of MCH in ground measurements is not the mean height of trees but the basal area weighted height of the trees within the plot, the so-called Lorey's Height of forest plot (Lefsky, 2010; Saatchi, Harris, et al., 2011). Hansen et al. (2017) found MCH, when used as a single predictor of AGBD in power law model, outperformed data-driven multiple linear regression in tropical biomes, but not in temperate and boreal biomes. Different ALS metrics will be more or less useful in different regions based on local environment (e.g. canopy closure, height distributions) and thus we do not provide a specific recommendation for which canopy metrics to include.

The selection of the geographic domain of ALS biomass model calibration will depend in part by the geographic domain of ALS coverage. ALS studies have fit AGBD models to lidar height metrics at local, regional and continental (toward global) scales. The concept of generalized models that can be applied over large areas is appealing but results in the literature have not been consistent. For example the approach used by Asner et al., (2012) corrected for regional wood density was not found to be useful in temperate forests (Duncanson, Dubayah, et al., 2015). Regional differences in wood density and complex forest structure have indicated local training of models is necessary (Coomes et al., 2017), however Knapp et al., (2020) found only a limited increase in model performance when moving from generalized to site-specific models in the tropics.

While next generation satellite lidar may help inform the development of generalized models to relate ALS metrics to AGBD, local and regional models typically produce higher accuracies and are able to capture relationships between AGBD and ALS metrics, which are driven by local or regional life history, floristic makeup, climatic and edaphic conditions. While **it is recommended** to continue research into generalized models for application to both large area ALS and

spaceborne lidar surveys, site-specific models remain more consistently reliable at present and ALS instrument and survey properties can also potentially cause systematic measurement differences (see Section 3.2.2). Therefore **it is currently recommended**, where possible, to use local to regional training of ALS biomass models for individual ALS campaigns to ensure they are locally unbiased.

### 3.2.4.3 Spatial resolution of ALS maps

Another critical consideration for AGBD modeling and mapping is spatial resolution. Airborne discrete return lidar can be processed at any spatial resolution (i.e. from sub-meter to km depending on the acquisition specifications). However, there is a minimum resolution at which AGBD data are meaningful, as spatial resolution of field observations are constrained to the individual tree level. Therefore the highest possible spatial resolution will be at the resolution of the largest tree crowns in a given area (which can span to approximately 0.25 ha in the tropics).

In the tropics, where large plots ( $\geq 0.25$  ha) are recommended, an ideal situation for biomass map calibration and validation is the development of multiple resolutions of AGBD models, such that a single site can be used to validate multiple resolutions of satellite products (see Section 3.2.5). Modeling and mapping at high ( $< 0.25$  ha) spatial resolution should be conducted with caution, largely because of the uncertainties outlined in Chapters 2 and 3. In general, models should be fit at the spatial resolution of field plots. Where only small field plots are available (e.g. 50 m plots) for ALS biomass model development, these models should only be applied to generate 50 m spatial resolution ALS biomass reference maps. If coarser resolution products are needed to match the spatial resolution of EO biomass maps for validation, native resolution AGBD estimates can be aggregated easily however care must be taken in aggregating per-pixel estimates of uncertainty (see Section 3.2.4.4).

Two examples are given in Figs. 3.4 and 3.5, where large (1 ha) field plots also had subplot information recorded and models could be fit at 25 m, 50 m and 100 m spatial resolutions. The first example is from the AfriSAR campaign (Fatoyinbo et al., in review). This campaign led to the production of ALS reference biomass maps from both large footprint waveform data (LVIS; Armston, Tang, et al., 2020) and small footprint discrete return data (Labriere et al., 2018). Fig. 3.4 illustrates the increase in uncertainty with decreasing spatial resolution when using LVIS. The best model performance was at 1 ha resolution, with an  $R^2$  of 0.82 (RMSE of 85 Mg ha<sup>-1</sup>), whereas the 0.25 ha resolution model had an  $R^2$  of 0.72 (RMSE of 114 Mg ha<sup>-1</sup>). These results are comparable to the discrete return lidar models of Labriere et al., (2018), which has an  $R^2$  of 0.79 (RMSE of 51.7 Mg ha<sup>-1</sup>) at 1 ha and an  $R^2$  of 0.60 (RMSE of 82.0 Mg ha<sup>-1</sup>) at 0.25 ha.

**Figure 3.4 Comparison of observed and modelled aboveground biomass at 0.25 (left) and 1.0 (right) ha scales.** The grey error bars represent 95% credible intervals in the LVIS predictions (y-axis) and the in situ estimates (x-axis).

A second example is shown from Barro Colorado Island in Panama (Fig. 3.5), which particularly highlights the impact of crown size on the relationship between spatial resolution and model accuracy. Again, we see increasing accuracy with decreasing spatial resolution from 20 m to 1 ha, which is attributed to a combination of edge effects, geolocation uncertainty in the field data, and large crown sizes.

**Figure 3.5** Ground plots of different size and lidar biomass models developed with mean top canopy height in tropical forests of Barro Colorado Island in Panama. The plots under the 1-m resolution Lidar data suggest that at scale of 20 m x 20 m (a), there is large bias in the model, but gradually at areas of 50 m x 50 m (b) and 100 m x 100 m (c) the model improves and the estimate of biomass can be done without significant bias.

In general, model accuracies will increase with decreasing spatial resolution. This is due to both decreases in uncertainties with respect to edge effects, and linking field plots to ALS data (see Sections 3.1 and 3.2.3.1 for details). However, these limitations are most prominent in tropical forests where geolocation uncertainties and colocation errors tend to be higher and large tree crowns increase edge effects (see Sections 3.1 and 3.2.3.1 for details). In some temperate and most boreal forests, higher resolution ALS biomass modeling and mapping will yield highly accurate models given lower canopy cover and smaller tree sizes. **It is recommended** that ALS biomass models always be developed at the spatial resolution of field plots. For densely forested areas (particularly tropical forests or areas with large crowns) where large plots ( $\geq 1$  ha) are

collected, these will ideally include sub-plot information (e.g., 0.0625 ha and 0.25 ha) so that multiple resolutions of AGBD models and maps can be produced.

#### **3.2.4.4 Characterization of uncertainty**

Propagation of uncertainty from field measurements through to satellite estimates is discussed at length in Chapter 4, but there are several considerations specific to the generation of ALS biomass maps that we discuss here to make practical recommendations on when uncertainty associated with a ALS biomass model can be assumed negligible and, when not, how to account for or mitigate its overall contribution.

Given the need to assess EO biomass products against reference estimates, rigorous approaches to characterization of uncertainty need to replace ad hoc approaches (Gregoire et al., 2016; Nelson et al., 2017). ALS biomass map uncertainty is typically assessed through comparison of model predictions with independent field estimates using techniques such as k-fold cross-validation using random or non-random (e.g. geographic transferability) subsets of the reference data (e.g. Dubayah et al., 2017; Duncanson et al., 2013; Ploton et al., in press). However it is not straightforward to use these results to estimate the error of estimated AGB means or totals across an area, which can be as small as an individual EO biomass product pixel.

Some studies have undertaken more detailed error propagation in the estimation of AGBD from ALS, accounting for in situ measurement and allometric model errors (e.g. Asner et al., 2012; Jucker et al., 2018), however these still lack spatially explicit estimates of uncertainty. Since in situ reference data used to calibrate ALS biomass models are not typically acquired using a probability sampling design, it is necessary to use a model-based inference framework to estimate uncertainty per pixel (Chen, Vaglio Laurin, et al., 2015). The formal framework for model-based inference is outlined in Section 4.2.2. It has been demonstrated in several studies in recent years (Chen et al., 2018; Esteban et al., 2019; Ståhl et al., 2016), but has not yet been adopted as standard practice by the remote sensing community due to a lack of software tools and/or statistical expertise.

The generation of reference ALS maps involves the use of multiple models. The first is the allometric model used to estimate plant biomass, which is described in detail in Section 2.2. The second is the model that relates the resulting estimates of plot AGBD to the ALS metrics as described in the preceding sections of Section 3.2. Ignoring the uncertainty from one of these models can result in underestimation of the true uncertainty (Chen, Vaglio Laurin, et al., 2015; Saarela et al., 2016, 2020). The uncertainty of ALS AGBD estimates for individual locations on an ALS map (i.e. pixels) from the second model can be decomposed into three independent error terms in a model-based inference framework: (i) the error variance estimates related to individual random errors of predictions; (ii) model parameter errors; and (iii) ALS measurement errors (Chen et al., 2016).

The mean AGBD when aggregating over small areas is straightforward and simply the mean of the ALS pixel estimates. Aggregating estimates of uncertainty over small areas to the spatial

resolution of EO biomass products (25 - 200 m) is more complicated. This is because the spatial autocorrelation of model errors needs to be taken into account when estimating the term for individual random errors of predictions over such small areas (McRoberts et al., 2018; Saarela et al., 2020). Studies that account for spatial autocorrelation in the individual random errors of predictions are scarce - Chen et al. (2016) is an exception - and has been acknowledged as a challenging problem (Saarela et al., 2020). This error component can be ignored over larger areas ( $\geq 1$  km; Saarela et al., 2018), which is the current approach for coarse resolution remote sensing biomass products such as GEDI (Patterson et al., 2019). However field plot sizes are often 0.0625 - 0.25 ha, which is smaller than the resolution of planned EO biomass products from the NASA NISAR and ESA BIOMASS missions (1 to 4 ha).

Measurement error in ALS metrics is almost always assumed to be zero, although Asner et al. (2012) assumed 5% and Chen et al. (2016) assumed 10%, albeit using unrelated approaches to error propagation. Some studies have indicated that measurement error can be significant for ALS derived canopy height (Disney et al., 2010) and cover (Armston et al., 2013; A. Fisher et al., 2020), particularly from older discrete return lidar datasets with low pulse densities and variable footprint sizes (Roussel et al., 2017). Therefore consistency in selection of sensor specifications and survey requirements **is recommended** as far as possible (See Section 3.2.2 for specific recommendations).

### **3.2.5 Comparison of EO products with ALS reference maps**

Assuming an ALS biomass (AGBD) reference map has been produced following the recommendations above, including reporting of uncertainties (ideally per-pixel), it can be used for both training of EO AGBD models or validation of EO AGBD products. The same basic principles for training and validation using ALS AGBD maps apply:

1. ALS reference biomass maps need to be spatially linked to EO products.
2. Statistical modeling of the relationship between the ALS AGBD reference map and the EO product data will be conducted, through the development of predictive models (for training) or evaluating the agreement between products (for validation).

It is critical to appreciate here that just as field plot estimates of AGBD do not represent true or direct estimates of AGBD (that would require plot level tree harvesting), ALS AGBD estimates will have even greater uncertainties since an additional modeling step is used in their generation. A key requirement here is that the ALS AGBD reference map is at least of greater quality than the EO map (GFOI, 2016, p. 125; Stehman, 2009). Thus, the uncertainty reporting recommendations for ALS AGBD reference products (described in 3.2.4.4) are particularly important.

#### **3.2.5.1 EO map product requirements**

ALS reference AGBD maps will typically need to be reprojected to the projection of the satellite product prior to validation. When assessing multiple satellite products, **it is recommended** to retain the EO biomass map products in their native map projection to avoid resampling, and generating ALS AGBD reference maps with spatial resolution, map projection, and grid alignment that match each of the EO biomass map products.

Ideally, per-pixel uncertainties will be available for the EO map products, consistent with recommendations in Chapter 4, however these are rarely available for existing products and impractical to generate (McRoberts, Næsset, Liknes, et al., 2019). In any case, it is important to recognize that independent estimates of product uncertainty can be calculated using high quality ALS AGBD estimates, that are still useful to identify regions with large systematic deviations from truth, guide product selection when multiple EO data products are available for a region, and to prioritize regions for methodological improvement.

### 3.2.5.2 Recommendations for validation

Several studies have suggested or applied methods for validating EO AGBD products using ALS AGBD reference maps, but at the time of writing there is no clear consensus or protocol to follow and results from different studies are often difficult to compare, partially because different reference estimates of AGBD were used. As stated in Section 5.2, the IPCC (2003, 2006) guidelines recommend that uncertainty and stability of EO AGBD products are to be assessed and reported for relative and absolute systematic deviation and confidence interval or RMSE, overall and by biomass class/range estimated using reference data of better quality.

The typical metrics used for assessing the uncertainty and stability of EO AGBD products are bias, relative systematic error ( $bias_R$ ), RMSE and relative RMSE. Since the ALS biomass reference maps contain uncertainties, RMSE is referred to here as Root Mean Squared Deviation (RMSD). The relative metrics are expressed as a percentage and consider that uncertainty may be small relative to the AGBD estimated. One may calculate bias,  $bias_R$ , RMSD and relative RMSD ( $RMSD_R$ ) over a user defined spatial domain as:

$$\begin{aligned}
 bias &= \frac{1}{N} \sum_{i=1}^N (\hat{y}_i - y_i) \\
 bias_R &= \frac{1}{N} \sum_{i=1}^N \left( \frac{\hat{y}_i - y_i}{y_i} \right) \times 100 \\
 RMSD &= \sqrt{\frac{1}{N} \sum_{i=1}^N (\hat{y}_i - y_i)^2} \\
 RMSD_R &= \sqrt{\frac{1}{N} \sum_{i=1}^N \left( \frac{\hat{y}_i - y_i}{y_i} \right)^2} \times 100
 \end{aligned}$$

where  $y_i$  is the ALS reference estimate of AGBD and  $\hat{y}_i$  is the EO map product estimate of AGBD. The calculation of these three terms is simple and straightforward if you do not consider uncertainty in the ALS reference and EO biomass maps. It's also important to note that under and over prediction at different biomass ranges may compensate each other in the calculation of bias and  $bias_R$ .

It is only possible to validate spaceborne estimates to the accuracy level of the ALS reference map (Duncanson et al., 2020; McRoberts, Næsset, Liknes, et al., 2019; McRoberts, Næsset, Saatchi, et al., 2019), however comparison of mean estimates are still useful to identify discrepancies in height and AGBD estimates that exist between different modeling approaches and underlying environmental conditions (Bolton et al., 2013; Duncanson et al., 2020; McRoberts, Næsset, Saatchi, et al., 2019; J. C. White et al., 2013). It is necessary that the ALS AGBD reference maps have absolute uncertainty that is small relative to the EO biomass products, therefore the ALS AGBD reference maps should be quality controlled and filtered such that only highly accurate products are used to estimate uncertainties.

There is no exact uncertainty requirement for ALS AGBD reference maps, and such a requirement would be undesirable as it will depend on spatial resolution and absolute value to AGBD. Presumably, all carefully constructed local ALS maps will be of higher quality than the EO products, but in particularly challenging areas (e.g. high biomass forests, areas with a dearth of training data, etc.) some local maps may have uncertainties approaching that of the EO product itself to be validated. In this case, the validation statistics would be meaningless. We suggest a comparison using bias,  $bias_R$ , RMSD and  $RMSD_R$  in EO biomass products over the domain of interest, as reported by the product authors, however it is necessary to account for the uncertainty of the ALS biomass reference maps in this process.

There are limited studies available that give insight into statistically rigorous methods to quantify the level of accuracy that can be determined by ALS biomass reference maps, with recent examples being McRoberts, Næsset, Liknes et al. (2019), McRoberts, Næsset, Saatchi et al. (2019) and Duncanson et al. (2020). McRoberts, Næsset, Saatchi et al. (2019) demonstrated an approach that took the form of a statistical hypothesis test that the mean AGBD estimates from the ALS reference and EO biomass map over a user defined spatial domain were not significantly different from zero. The approach used hybrid inference (see Chapter 4) to account for both sampling variability and non-negligible errors in the ALS biomass reference map, and made important recommendations on uncertainty reporting requirements for EO biomass maps.

Duncanson et al. (2020) presented an alternative approach, where confidence intervals were compared between simulated EO AGBD estimates and reference ALS AGBD estimates at the native resolution of each EO product (25 m - 100 m). It was not possible to evaluate over a spatial domain using the approach of McRoberts, Næsset, Saatchi et al. (2019), however confidence intervals were available for both the ALS reference or EO biomass maps. The metrics used were the percentage of ALS and EO estimates over a spatial domain that had overlapping confidence intervals. This allowed large systematic deviations in the EO biomass map to be detected across environmental gradients, but only where the EO biomass estimates were outside the range of the ALS reference map confidence intervals.

The generation of ALS AGBD reference maps and associated uncertainties at multiple spatial resolutions should account for differences in the spatial resolution of EO biomass products, such as those from GEDI, NISAR and BIOMASS, however their interpretation should be caveated by the spatial scale analyzed. It is well accepted that biomass model fitting errors reduce with

increasing plot size or resolution (Hall et al., 2011; Labriere et al., 2018; Zolkos et al., 2013), largely because of the reduction in variance of reference AGBD estimates with increases in spatial scale (see Section 3.1). Calibration and validation results for EO biomass products at their native spatial cannot be directly compared where different, therefore for EO biomass product intercomparison **it is recommended** to aggregate to the finest common spatial resolution possible.

Key to the application of ALS in validation of global EO products is consistency in the definitions, measurement methods, AGBD modeling techniques, and statistical inference frameworks used to characterize uncertainty. Given the diversity of ALS instruments and in situ protocols used in different biomes it is necessary to be adaptive, but care must be taken to ensure the integrity of core measurements (e.g., ALS canopy height and cover) are maintained over time as instrument specifications, survey configurations and data processing methods advance. Otherwise validation efforts will continue to be one-offs, ALS biomass models will not be spatial and temporally transferable or consistent.

We emphasize the need to minimize uncertainty in ALS reference maps as far as practical, but these uncertainty estimates need to be realistic. A tool for propagation of in situ and ALS measurement and model errors (see Chapters 2 and 4) to the resolution of EO AGBD products that is accessible and standardized is presently unavailable. Stratifying validation by land cover, geographic extent, environmental gradients (e.g., slope, canopy cover) and AGBD range/class will enable users to estimate the uncertainties of multiple available EO biomass products within their specific domain of interest. **It is therefore recommended** that a tool be developed with a user-friendly interface for comparison of local maps derived from ALS to global maps derived from EO at multiple spatial resolutions and by user defined strata.

### 3.2.6 Summary and current knowledge gaps

Large and small footprint ALS have long been established as tools for near direct estimation of canopy height and cover, and subsequently through empirical modeling AGBD. Both capture landscape scale variation in structure, providing a bridge between EO and local scale observations (UAV-LS, TLS, field). Large footprint lidar systems (e.g. NASA LVIS) enable rapid and large area wall-to-wall or transect acquisitions (e.g. entire countries in some cases) but are of limited availability, however small footprint ALS systems are now capable of this scale of acquisition as well.

A key issue for global validation of EO products are practical and logistical constraints on ALS data acquisition. Government restrictions on ALS data availability (e.g. China, India) and flight authorization (e.g. Brazil) can make access to existing data or acquisition of new data difficult. Depending on transit distance and areal coverage required, ALS data acquisitions can be expensive, with estimates on the order of \$250 – \$600 km<sup>2</sup> (in US dollars) for small footprint ALS (Réjou-Méchain et al., 2019). Non-commercial instruments such as NASA facility instruments can acquire much larger areas than current commercial small footprint ALS systems for the same cost, however they are not as readily accessible and may incur large transit costs.

**The following are recommendations** when producing a reference ALS AGBD map for EO biomass map validation. These are in addition to recommendations on linking field plot data with ALS data that are aimed at minimizing the impact of geolocation error and plot size (Section 3.2).

1. Use recent, high-quality, well-validated lidar instruments and survey configurations
  - Photon counting instruments are not yet mature enough for routine biomass estimation or tested across a wide range of ecosystems, therefore are not recommended
  - Small footprint waveform and discrete return instruments are both useful provided sufficient point density ( $\geq 4$  pulses  $m^{-2}$ , preferably  $\geq 8$ ), small footprint size ( $< 30$  cm), a maximum off-nadir scan angle  $< 15^\circ$ , and preferably no dead-time between returns ( $\geq 4$  returns per pulse)
  - Adhere to QA/QC protocols and data delivery specifications recommended by existing national programs - including TERN Australia, USGS 3DEP, and NSF NEON - for forest applications
2. Acquire wall-to-wall data that are spatially and temporally coincident with field plots
  - Transects still fill an important niche for large area sampling and validation of current spaceborne lidar observations
  - Wall-to-wall data are recommended coincident with field plot data over a large enough area (minimum 3 x 3 km, preferably larger) to capture landscape scale variation in canopy structure and AGBD and enable scaling from fine to coarse spatial resolution of EO biomass products
  - Acquisition should take place during the same season as field collection (preferably leaf-on in deciduous forests)
  - ALS acquisition should be as close in time as practicable to field acquisitions
    - In snow-free and maximum leaf-on conditions (where deciduous species are present)
    - Before plot acquisition where possible to aid in plot placement through stratified sampling by forest structure measurements
    - Ideally within one year of plot measurement to minimize change (although a longer time gap is acceptable in slow growing forests with no detected disturbance)
3. Develop local AGBD models using an area-based approach
  - Estimation of AGBD from ALS is indirect, therefore model calibration requires that *in situ* reference data are sampled across the full range of AGBD and the ALS metrics used as predictors.
  - The use of a stratified sampling approach is recommended, preferably with strata that are defined using the ALS structure metrics themselves
  - Individual tree-based AGBD approaches currently introduce additional uncertainty and are less mature and generalizable than area-based approaches.
  - Adopt simple parametric models that minimize the number of height, cover and vertical structure metrics used, particularly when a limited number of field plots are available

- Evaluate model performance using geographic cross-validation (e.g. Ploton et al., in press)
- 4. Adopt a statistically rigorous framework for reference map generation
  - Ideally use a formal statistical inference framework (see Chapter 4 for details) to propagate errors from allometric (see Chapter 2 for details) and ALS models
  - If possible, develop ALS biomass reference maps at the resolution of EO data products to simplify error propagation
  - Provide per pixel estimates of uncertainty in the form of mean squared errors to accompany the per-pixel mean estimates of AGBD
  - Clearly report which error sources are included or omitted in any error propagation document the process followed.

We have identified the following gaps in methods development and tools to enable systematic validation with a global set of linked field plots and ALS AGBD reference maps:

1. A quality control framework for AGBD map production that includes:
  - improved uncertainty estimates at the pixel level that account for multiple sources of error (see Chapter 4)
  - methods to aggregate AGBD uncertainties from ALS pixel level to the spatial resolution of EO map products
  - evaluation of ALS metric repeatability and biomass model performances when applied to ALS datasets from new instruments or acquisitions that are not coincident with field plots
2. A tool for propagation of *in situ* and ALS measurement and model errors (see Chapters 2 and 4) to the resolution of EO AGBD products that is accessible and standardized
3. A tool for comparison of local maps derived from ALS to global maps derived from EO at multiple spatial resolutions and by user defined strata

# Chapter 4: Characterization and Propagation of Error

Stephen Roxburgh and Ronald E. McRoberts

Quantifying the accuracy of estimates of forest aboveground (dry) biomass (AGB) is necessary for understanding and mitigating the impacts of climate change across a range of spatial domains, from individual forest plots or stands, through to regional, national or even global scales (GFOI, 2016). This chapter is concerned with the steps required to calculate the accuracy of map-based biomass estimates, inclusive of errors associated with reference data such as plot-level biomass (Chapter 2), and errors associated with the models that are used to combine that reference data with remote sensing products to create maps of AGB (Chapter 3). Here we define reference data as the fundamental estimates from which statistical inference is made, typically plot-level AGB from forest inventories. Reference data are often assumed to be error free, but here we also consider the case of 'imperfect' reference data, that are themselves subject to uncertainty, which is always the case for forest AGB. This is an important distinction, as the nature of the reference data determines the statistical inference methods that can be used, with associated differences in the calculation of biomass and its uncertainty.

Error propagation is the term given to the identification and appropriate accounting of all relevant error sources contributing to an estimated quantity, with smaller levels of error associated with greater accuracy, and where uncertainty includes both bias (= systematic error) and precision (Figure 4.1). Estimating bias can be problematic in practice, as it requires knowledge of the 'true' underlying value (Figure 4.1), which in many cases is unknown. Sources of bias with respect to AGB estimation that are amenable to estimation are instrument error, such as incorrectly calibrated weighing scales that consistently under- or over report the mass of harvested tree components when developing allometric models (Section 4.1.1), and model predictions with systematic error arising from incomplete or inappropriate model specification (Section 4.2.1).

The second component of uncertainty, precision, quantifies the spread around a given estimate, and is usually the primary focus of error propagation studies. It is useful to recognise that precision includes two broad sources of uncertainty. The first is uncertainty arising from natural variability, such as genotypic or phenotypic variability in the size of individuals of the same age and species, or spatial variability in forest biomass due to e.g. edaphic factors or topography. The second source is often called random error, with the implication that it can potentially be reduced by e.g. improved measurement protocols, more efficient sampling strategies, or increased sample sizes. Uncertainty arising from variability and uncertainty arising from measurement errors can be difficult to disentangle, and thus they are often treated together. A wide range of analytical and Monte Carlo techniques have been applied to forest biomass error propagation (e.g. Breidenbach et al., 2014; I. F. Brown et al., 1995; Case & Hall, 2008; Chave et al., 2004; Chen, 2015; Chen et al., 2016; Chen, Laurin, et al., 2015; Cohen et al., 2013; Gertner & Köhl, 1992;

Holdaway et al., 2014; Keller et al., 2001; Lehtonen et al., 2007; Magalhães & Seifert, 2015a; Magnussen et al., 2014; Mavouroulou et al., 2014; McRoberts et al., 2015; McRoberts & Westfall, 2016; Melson et al., 2011; Molto et al., 2013; Ngomanda et al., 2014; D. L. Phillips et al., 2000; Picard et al., 2015, 2016; Réjou-Méchain et al., 2017; Roxburgh & Paul, 2019; Yanai et al., 2010). With regard to international greenhouse gas accounting, the IPCC specifies two good practice guidelines for greenhouse gas (GHG) inventories: (i) “neither over- nor underestimates so far as can be judged” and (ii) “uncertainties are reduced as far as practicable” (GFOI, 2016, p. 15). Therefore when developing new or using existing biomass maps, estimates based on those maps are currently required to comply with these guidelines. In general terms this means ensuring that estimates are either obtained or evaluated using unbiased estimators (satisfying criteria (i)), and that all of the key error sources are recognised and accounted for, and that the methods applied are rigorous, appropriate, and quantifiable (satisfying criteria (ii)). In particular, the aim is to construct inferences in the form of confidence intervals for the estimates, for either whole-map biomass or for sub-map areas or specific locations. In a formal statistical sense, “inference” here means expressing a result in probabilistic terms, i.e., a 95% confidence interval in the form  $\hat{\mu} \pm t_{0.95} \cdot SE(\hat{\mu})$ , where  $\hat{\mu}$  is the estimate of a parameter such as mean biomass, and  $SE(\hat{\mu}) = \sqrt{\widehat{Var}(\hat{\mu})}$  if the estimator is unbiased (Section 4.2.1), or  $SE(\hat{\mu}) = \sqrt{MSE(\hat{\mu})}$  if the estimator is biased (Section 4.2.2) (McRoberts, Næsset, Liknes, et al., 2019).

**Figure 4.1 The accuracy of an estimate comprises two components.** (i) Precision quantifies the variability around the estimated value. (ii) Bias quantifies the degree to which the estimated value deviates from the true (but often unknown) population value.

Two broad forms of inference have been applied to calculate the desired biomass estimate ( $\hat{\mu}$ ) and its uncertainty ( $SE(\hat{\mu})$ ) (McRoberts, Næsset, Saatchi, et al., 2019). The first, design-based, requires a probability sample of reference data that is subject only to negligible uncertainty. The most straightforward application of design-based inference is where sample points are located independently and at random in space, and where  $\hat{\mu}$  and  $\widehat{Var}(\hat{\mu})$  are calculated using the traditional simple expansion estimator (EXP) (also known as the simple random sampling (SRS) estimator). This, and other sampling designs such as systematic sampling and stratified sampling and their associated estimators, are discussed in Section 4.2.1. The main limitation when using simple design-based estimators for total-area biomass (or total-area biomass density, i.e. biomass expressed on a per-unit area basis) is that the method does not produce spatially explicit maps of AGB, i.e. with sub-area resolution. To overcome this limitation model-assisted difference estimators (McRoberts, 2010; McRoberts et al., 2013) have been employed, whereby the

probability samples are combined in a model with auxiliary information, such as remotely sensed data, from which AGB maps are constructed. Note that model-assisted estimators are still considered part of the design-based paradigm because their validity rests on the underlying probability-based sample, rather than the validity of the model linking the probability samples with the auxiliary data. Model-assisted estimators are also discussed in Section 4.2.1.

The second form of inference that can be applied is model-based, which can use either probability or non-probability samples of the reference data, and when combined with spatial auxiliary data (such as obtained from remote sensing) can also produce maps of biomass. In contrast to design-based inference, the validity of the model-based estimator rests on the correctness of the model, rather than the sampling design (Section 4.2.2). Design-based and model-based estimators are fundamentally different paradigms, with different mathematical procedures for the handling of uncertainty. One similarity between them, however, is that both require that the reference sample yields reference biomass estimates that are error-free, or that are at least characterized by negligible uncertainty.

Almost always, however, plot-level reference data are subject to non-negligible uncertainty, for example when plot-level biomass is predicted using allometric models (Section 2.1). Numerous studies have shown the uncertainty of such biomass estimates to be non-negligible (Breidenbach et al., 2014; Chave et al., 2004; Réjou-Méchain et al., 2017; Roxburgh & Paul, 2019; Ståhl et al., 2014). To account for such 'imperfect' reference data, hybrid inference, which combines elements of design-based and model-based inference, can be applied to AGB estimation and mapping to fully comply with the IPCC criteria. Hybrid inference is discussed in Section 4.2.4.

The chapter is structured into two sections. The first (Section 4.1) provides an overview and brief description of the sources of uncertainty that need to be considered when generating biomass estimates. The underlying assumption is that creating a biomass map involves (1) the collection/assimilation of field data (typically plot-based inventory data) and other information for predicting stand-level biomass from allometric models - referred to as the reference data; and (2) the use of a model that combines auxiliary spatial data (typically derived from remote sensing) with the reference data to construct a biomass map. Uncertainties are present at both steps (1) and (2), and Section 4.2 describes in greater detail the approaches that can be used to propagate those uncertainties throughout the chain of calculations.

## **4.1 Sources of uncertainty**

There are a wide range of uncertainties associated with the construction of biomass maps, and which can manifest as either precision or bias (Tables 4.1a & 4.1b). Bias can potentially occur when making measurements, such as weighing whole trees or tree sections with instruments that have not been properly calibrated, or poor field techniques leading to consistent over- or underestimation of quantities such as stem diameter during forest inventory. When detected, it is preferable to correct the affected data for systematic errors prior to further analysis, thus minimising the risks of measurement-based bias propagating through the chain of calculations.

Tables 4.1a & 4.1b therefore focus on sources of precision uncertainty, with the assumption that any systematic measurement error issue has been resolved.

This section describes the various sources of uncertainty that need to be considered, but does not provide specific details for the estimation and propagation of those uncertainties, which can be achieved by a range of methods such as analytical approximations, Monte Carlo methods, or a combination of the two. In Section 4.2 a generic Monte Carlo procedure is provided, in the context of hybrid inference, to illustrate how the various sources of uncertainty can be propagated through to the final map product. There are two main calculation steps, with uncertainties arising at several points.

#### **4.1.1 Uncertainties in the generation of reference data**

Reference data typically comprise estimates of biomass made at local scales, such as forest inventory sample plots. When allometric models are used to estimate the biomass within a sample plot there are a number of potential sources of uncertainty. The first are the errors associated with the development of the allometric model itself (Section 2.2), which includes errors associated with the measurement of the dependent variable (usually either individual tree dry mass, or individual tree volume; Table 4.1a, source A.1), the measurements of the independent variables (e.g. tree DBH, height, wood density; Table 4.1a, source A.2), and errors associated with the estimated model parameters (Table 4.1a, source A.3). Of these, allometric model parameter estimation errors have been most studied, with the key quantity for error propagation being the model parameter variance-covariance matrix (Cohen et al., 2013; McRoberts & Westfall, 2016). In general, increasing the sample size of individuals on which the allometric model is based is a sound strategy, as larger sample sizes increase the precision of the estimates of the model parameters (Chave et al., 2004; Roxburgh et al., 2015; van Breugel et al., 2011).

One overlooked and potentially important source of uncertainty during allometric model development involves errors that simultaneously affect multiple individuals, thus leading to non-negligible covariance, and increased uncertainty (Ståhl et al., 2014; Yanai et al., 2010). For example when predicting dry biomass, moisture content correction factors to convert fresh mass to dry mass are usually based on oven-drying samples collected from a small subset of the population, but are applied to the population as a whole (Paul, Roxburgh, et al., 2017; Roxburgh & Paul, 2019). Thus, any error in the moisture content correction factor will be simultaneously applied to multiple individuals. A Monte Carlo procedure for accounting for the errors associated with allometric model development is provided in McRoberts et al. (2016) and Roxburgh and Paul (2019).

**Table 4.1a Summary of sources of uncertainty when estimating plot-scale aboveground biomass through developing and applying allometric models to data collected from inventory sample plots.**

Calculation step	Source of uncertainty	Brief description
A. Allometric model development	A.1. Dependent variables (volume, or dry mass; where dry mass = fresh mass x moisture content correction).	Allometric models predict either per-tree volume, or per-tree dry biomass. For either dependent variable there may be errors associated with the required measurements.
	A.2. Independent variables, e.g. stem diameter, height.	Similar to A1, there may be measurement errors associated with the independent variables that are used as biomass (or volume).  Measurement errors may be either systematic (bias) or affect precision, through e.g. random measurement errors, or natural variability.
	A.3. Allometric model parameter uncertainty.	Uncertainty arising from model parameter estimation as part of the model fitting procedure.
B. Allometric model use	B.1. Independent variables, e.g. stem diameter, height.	As per A.2., there may be errors in the measurement of the model independent variables. Forest inventory typically involves the measurement of 100s-1000s of individuals, hence providing opportunity for such errors to compensate. Although large sample sizes can reduce random sampling error, often there will be natural variability that cannot be reduced by increased sampling effort.
	B.2. Allometric model prediction (residual) error.	Even if term A.3. can be minimised through e.g. increased sample sizes on which the allometric model is based, there is often large residual variation around the fitted relationship, simply because of natural variability (e.g. trees with the same stem diameter can have widely differing biomass).
	B.3. Conversion of volume to biomass (and biomass to carbon).	Volume estimates need to be converted into dry mass, typically by multiplying by wood basic density, which is variable within-individuals, within-species, and between species. Similarly, if biomass needs to be expressed in units of carbon, then this requires multiplying by tissue carbon concentration, which is although usually treated as a constant (typically in the range 0.45 – 0.55) may also be uncertain.
	B.4. Alternative allometric model choice error.	In some circumstances, especially when using multi-species (or generalised) models, there may be a choice of more than one model for a given situation, with often differing predictions between models.
C. Sample plot area	C.1. Plot area	For each sample plot the summation of individual tree biomass estimates and the propagation of the uncertainties A.1. – B.4. yields plot-level estimates of total biomass and uncertainty. To convert this to per-unit-area requires division by the plot area, which itself may be uncertain through e.g. errors in locating plot boundaries.

**Table 4.1b.** Summary of sources of uncertainty when estimating large-area or mapped biomass

Calculation step	Source of uncertainty	Description
D. Sampling error	D.1. Spatial variability in biomass.	With design-based inference sample plots can be spatially distributed using any of multiple probabilistic sampling designs including e.g. simple random, stratified with simple random sampling within strata, or using schemes that seek to distribute plots more uniformly (e.g. systematic sampling, restricted random sampling). Because the world is spatially variable (at all scales) and the sampling intensity is typically low relative to the total areal extent of the population, sampling error is often an important source of uncertainty.
E. 'Predictive biomass model', to predict biomass from auxiliary data.	E.1. Independent variable errors	Mathematical models can be used to predict measured biomass (the reference data) from ancillary data, which typically comprises spatial layers such as rasters, with pixel-to-pixel variability. E.1 captures errors in the independent variables (i.e. the auxiliary data) of the predictive biomass model (e.g. remote-sensing-derived metrics; spatially interpolated climate data). There may also be location/georeferencing errors in the auxiliary data.
	E.2. Predictive biomass model parameter uncertainty	In the same way that there is uncertainty in fitted parameters of the allometric model (A.3), there will also be parameter uncertainty in the predictive biomass model.
	E. 3. Predictive biomass model prediction (residual) error.	As with the allometric model prediction error (B.2), the biomass model makes predictions only imperfectly, which is quantified by the model residual error.
F. Total (regional) biomass	F.1. Uncertainty in mapped total spatial extent	To convert estimates of large-area carbon density to total carbon stock requires multiplying by the regional area (e.g. the area within which the reference data plots were located). If there is uncertainty in the total area (e.g. through mapping errors of boundaries) this should also be included in the conversion. When areas are calculated from the summation over pixels/map units from an existing mapping product, then this error is likely negligible.

The next group of uncertainty sources are those associated with the application of the allometric models for biomass prediction. The most familiar of these is the allometric model prediction error (Table 4.1a, source B.1), and this source of uncertainty is central to all studies of the propagation of errors using allometric models (Réjou-Méchain et al., 2017). Increased allometric model sample sizes can help reduce this error source through reducing model parameter estimation uncertainty, but there will always be natural variability in the mass of individual trees of the same diameter that cannot be reduced by increased sampling effort, and this source should therefore be included in any analysis. Allometric model prediction errors are assumed to be independent between the individuals that are being predicted, hence large inventory sizes can help reduce the absolute magnitude of this source through providing opportunities for the errors across individuals to cancel.

There are also measurement errors associated with the independent variables that are used to predict individual biomass, such as DBH and tree height (Section 2.1, Table 4.1a, source B.2). Field experiments have suggested minimal systematic error in diameter measurements, but with average precision (expressed as coefficient of variation) in the range 3-7% (Holdaway et al., 2014;

Paul, Larmour, et al., 2017). Errors in the independent variables of a simple linear regression can cause 'dilution bias' (Réjou-Méchain et al., 2014), reducing the estimate of the regression slope; for nonlinear or more complex models such as random forest the extent of the bias is difficult to predict, and may require Monte Carlo or other randomisation techniques to assess.

If the allometric model predicts total tree volume, then conversion to biomass requires an estimate of the species wood basic density, which is usually imperfectly known given wood density varies within individuals, within species, and between species (Table 4.1a, source B.3). Although the focus is the estimation of biomass, greenhouse gas accounting usually requires conversion of AGB to carbon (or carbon-dioxide equivalents). The conversion from dry mass to carbon is usually accomplished by multiplying dry mass by approximately 0.5, under the assumption the mass fraction of carbon in dry wood is constant. However, Martin et al. (2018) in a global review have suggested the carbon fraction is more variable than often assumed, and they provide data that could be used to assign uncertainty values to this estimate (Chave et al., 2009 also reviewed this).

The final source of error associated with the use of allometric models to predict biomass is that due to the choice of alternative allometric model, when multiple competing allometric models are available for a given region (Table 4.1a, source B.4). Studies that have investigated the uncertainty that arises due to allometric model selection have shown this to be a potentially significant source of error (e.g. Chave et al., 2004; Mavouroulou et al., 2014; Melson et al., 2011; Picard et al., 2015, 2016). Quantifying error due to allometric model selection can be achieved by repeating the biomass estimation using each alternative model in turn, or if multiple model choices are available across a number of species, by selecting models at random within a Monte Carlo analysis. A more sophisticated approach weights the contribution of each model relative to the likelihood that it best represents the underlying data, using the method of Bayesian Model Averaging (BMA) (Picard et al., 2015). A comprehensive description of BMA in the context of biomass prediction is given by Mavouroulou et al. (2014), including R code listings for conducting the analyses.

The sources of error considered thus far impact on the biomass prediction of an individual shrub or tree, and its uncertainty. Aggregation of the individuals within the sample plot simply requires summing each individual's predicted biomass, and for the error propagation, summing each individual's error variance to yield the total biomass variance for the plot. However for most mapping purposes the biomass density of the plot is required (e.g. t AGB ha<sup>-1</sup>), rather than the total biomass (e.g. t AGB). This requires dividing the total biomass estimate by the plot area, which itself may be an uncertain quantity as marking out plots can lead to errors associated with plot boundaries being obscured by vegetation or topography, or GPS location errors (Sections 2.1, 3.1, Table 4.1a, source C.1). Plot area errors can also arise due to topography, when plots are projected horizontally (Gertner & Köhl, 1992).

#### **4.1.2 Uncertainties in constructing maps of biomass and large area biomass estimates**

A statistical estimator must be applied to the reference data from Step 1 in order to estimate biomass and its uncertainty for the region within which the sample plots were located, and to generate maps of biomass. As noted in the introduction there are two broad classes of statistical estimator that can be applied: design-based and model-based, with four variants considered in this chapter (design-based, design-based model assisted difference, model-based, and hybrid). The appropriate inference method to use depends upon the nature of the reference data and the details of how it was obtained, specifically, whether the sample was probability-based (e.g. as part of a designed sampling program) or non-probability-based (such as opportunistic or non-randomly located sample plots); whether the reference data can be considered to have non-negligible uncertainty or not; and whether there exists suitable auxiliary data to be combined with the reference data to allow map(s) of biomass to be generated via a spatial predictive biomass model. The four variants of inference are described in greater detail in the next Chapter, together with an explanation of the different assumptions and calculations required to estimate both biomass and its uncertainty. A decision-tree to guide users on the most appropriate inference method to use based on available information is provided in Figure 4.2.

If the sample plots from which the reference data were calculated comprised a probability-based design (such as simple random sampling, stratified random sampling or systematic sampling), and the various sources of uncertainty discussed in Step 1 can be considered negligible, then traditional design-based statistical estimators can be used to estimate a total biomass for the entire region (Section 4.2.1), though without additional information traditional estimators cannot be used to construct biomass maps with sub-regional resolution.

The primary source of uncertainty associated with a design-based probability sample is sampling error (Table 4.1b, source D.1). Sampling error arises because, for most populations of interest, only a relatively small sub-sample of individuals are able to be measured: thus, a hypothetical experiment with repeated sampling of the same population under the same randomisation scheme but varying only the plot locations will yield variable results, simply because each sample experiment will, by chance, tend to include a different set of individuals. The key contributors to sampling error are the spatial extent of the population, the spatial variability in biomass over the target population, and the sampling design, where the sampling design includes plot size, plot shape, plot area, the total number of plots, and the method used to locate plots in space (e.g. simple random, or other sampling methods designed specifically to provide a more representative coverage). Because spatial variability is ubiquitous and the sampling intensity is typically small relative to the total areal extent of the population, sampling error is usually a non-negligible source of uncertainty, and is often the dominant term.

Whilst the reference data on their own cannot construct a biomass map, they can be combined with auxiliary data to provide maps of biomass and biomass uncertainty; this forms the basis for the design-based model-assisted difference and regression, the model-based and hybrid inference methods (Sections 4.2.1 - 4.2.3).

Combining spatial auxiliary data such as that derived from remote-sensing with the reference data within a predictive model provides the mechanism for constructing maps of biomass and their uncertainty. Many types of predictive models have been used, such as linear and nonlinear regression (e.g. McRoberts et al., 2016), or non-parametric machine learning algorithms such as random forest (e.g. Roxburgh et al., 2019). Similarly, many different types of spatial auxiliary data can be utilised as predictor variables, such as mapped climate data, reflectance data from a range of aerial and satellite sensors, and active data such as lidar and radar. Whilst there are many choices for the form of the model and for the choice of predictor variables used, the basic goal is the same: to use the auxiliary data to predict the biomass in those locations where reference data were not collected, by training (= calibrating) the model using the available reference data. Regardless of the complexity of the modelling approach adopted or the range and type of auxiliary data used, there are two sources of uncertainty that need to be considered (in addition to any uncertainty in the reference data used as the model dependent variable, which is discussed in Section 4.1.1).

**Figure 4.2 Decision tree to determine the most appropriate inference method for estimating biomass and its uncertainty.** The grey bar denotes the point at which auxiliary data (e.g. remotely sensed data) are combined with the reference data to create a predictive biomass model that can then be used to predict sub-regional (e.g. pixel-level) biomass. Note that model-based methods can utilise either probability- or non-probability sampled reference data.

The first source of uncertainty is the auxiliary data themselves, such as the remote-sensing derived metrics or other spatial information (Table 4.1b, source E.1 ). Whilst a wide range of remote sensing products can be related to biomass, such as spectral signals from optical sensors, or tree heights predicted from lidar or SAR, these data may themselves be uncertain. Potential sources of error include those of registration and alignment, and uncertainties in the data products themselves, for example in the prediction of tree height from lidar returns due to spatial variability in the returned points (in three dimensions) and errors associated with determining the ground level (GFOI, 2016).

The second and third sources of uncertainty arise because the relationships between the auxiliary data and the reference data are imperfect, and thus in the context of parametric regression subject to uncertainty in the model parameter estimates (Table 4.1b, source E.2), and model prediction errors (Table 4.1b, source E.3). These are analogous to sources A.3 and A.4 in Table 4.1a that were associated with the development of the allometric model. When using non-parametric modelling these error sources may need to be estimated via randomisation or Monte Carlo techniques.

The final calculation step involves obtaining an estimate for the total biomass (or biomass density) of the region as a whole. If the reference data are in units of biomass density (i.e. t AGB ha<sup>-1</sup>) then the absolute total biomass for the region requires multiplying the regional-scale mean biomass density by the regional area (ha). In cases where auxiliary data is derived from other mapping products, then the total areal extent may be known with greater accuracy, such as summing over pixels in a raster, then it is possible this uncertainty source could be assumed to be negligible. However if the total area was based on ground surveys, or manually translated from e.g. aerial photography or printed maps, then this error source may be non-negligible, and should be included in any calculations. This can be addressed in an analogous way to the handling of individual plot area errors described in relation to error source C.1.

### **4.1.3 Assessing the importance of error sources**

Given the wide range of sources potentially contributing to the total uncertainty it is natural to ask which ones might be considered negligible and thus could be excluded from analysis, and which ones are non-negligible and should be included. Answering this question is problematic as it depends upon the information that is available (e.g. whether there are sufficient statistics describing the auxiliary data to allow model-based uncertainty estimates to be made, Section 4.2.2), or whether uncertainty information obtained from other studies could be used (such as applying field-based measurement errors obtained in one forest type or region to the error analysis of another; Figure 4.2). It also depends on whether the negligible/non-negligible effects of sources of uncertainty are being assessed in either absolute or relative terms. In particular, the effects of a source such as allometric model prediction uncertainty (source B.2) can be considered non-negligible in absolute terms whenever they are non-zero. However, even if they are non-negligible in absolute terms, they may still be negligible relative to other sources in application when assessed against some standard. For example, researchers often find that the effects of allometric model prediction uncertainty are negligible relative to the effects of sampling

variability (Chave et al., 2004; McRoberts et al., 2015; Roxburgh et al., 2019); uncertainty sources may also be negligible relative to the biomass quantity being estimated, which can be quantified as the coefficient of variation (i.e. the square root of the error variance divided by the mean biomass).

The IPCC (2003, 2006) provides some guidance here, making it clear that setting hard requirements for accuracy (such as requiring estimates to be within  $\pm 10\%$  of the mean 95% of the time) is neither practical nor desirable, and that the purpose of undertaking uncertainty analyses is not to dispute the validity of the estimates, but to help prioritise efforts to improve the accuracy of inventories into the future, and to guide decisions on methodological choice (IPCC, 2000, p. 6.5). Within this context, and consistent with the IPCC guidance of providing neither over- nor underestimates so far as can be judged with uncertainties that are reduced as far as practicable, a practical approach is to first identify the appropriate inference framework (Figure 4.2), and then to identify all error sources associated with the available data and models (Section 4.1), and be as comprehensive as possible in including them within the error propagation analysis (Section 4.2).

## **4.2 Propagating errors from measurements to maps**

A summary of the three broad inference methods that can be used to combine reference data and spatial auxiliary data to produce maps of biomass and associated uncertainty is provided in Table 4.2. The first two (Design-based, Model-Based) assume reference data (e.g. plot-level biomass) are measured with negligible uncertainty, which may or may not be the case when biomass is estimated by allometric models (McRoberts & Westfall, 2016; Réjou-Méchain et al., 2017 and Section 4.1). The third (Hybrid inference) combines elements from both design-based and model-based inference, and can accommodate 'imperfect' reference data with non-negligible uncertainty.

**Table 4.2. Summary of three inference methods for biomass estimation.**

Inference method	Reference data	Estimator	Notes
	E.g. plot-scale biomass, with plots distributed within a finite region.	A procedure that uses reference data to infer the biomass of the full region.	
1A. Design-based estimator	A probability sample, with values observed with negligible uncertainty.	Traditional statistical inference using e.g. simple random expansion (EXP) estimators for mean biomass and its variance (reflecting sample error; Source D.1, Table 4.1b).	Traditional statistical inference can provide a biomass estimate of the total region and its uncertainty, but cannot generate a map with additional data.
1B. Design-based model-assisted difference estimator	As per 1A above.	Utilises auxiliary data, typically in the form of remote-sensing derived spatial layers, to refine the mean biomass and variance estimates from 1A.	This method can generate a biomass map with sub-area resolution, by using the auxiliary data to predict biomass in locations other than where the reference data were collected.
2. Model-based estimator	Either a probability or non-probability sample, with values observed with negligible uncertainty.	Estimation using a model that combines the reference data with auxiliary information.	Can generate a biomass map. In common with 1B the reference data is used to calibrate a model for predicting biomass, but with the mean biomass and mean squared error (MSE) <sup>1</sup> based on attributes of the model. For this estimator the validity of the estimates are based on the validity of the model, rather than the validity of the probability-based reference data sample.
3. Hybrid (of design-based & model-based estimators).	A probability sample, with values observed with non-negligible uncertainty.  Non-negligible uncertainty typically arises from the use of allometric models to predict plot biomass.	Estimation using a model that combines the reference data with auxiliary information, in addition to the sampling error derived from the probability sample.  Overall uncertainty is a combination of model prediction uncertainty, reference data uncertainty, and sampling variability	Construction of a biomass map, with comprehensive accounting of contributing sources of uncertainty

### 4.2.1 Design-based estimators

Design-based estimation is based on a probability sample of reference data that is collected within the region of interest. A probability sample requires that some form of randomisation was involved in the selection of the sampling units, and that the ‘inclusion probabilities’, i.e. the probability of the population units being included in the sample, are positive and known. An additional requirement is that each population is assumed to have only a single value, apart from negligible measurement or other errors.

<sup>1</sup> A mean-squared error (MSE) is calculated here rather than variance, as there is potential for the model to be biased. If the model is unbiased then the MSE equals the variance (McRoberts, Næsset, Saatchi, et al., 2019).

There are a number of possible sampling designs, the most familiar of which is simple random sampling where population units are selected independently and at random. This is often considered the baseline methodology because it is easy to apply and intuitive, and the simple expansion estimator (EXP, described below and sometimes called the simple random sampling estimator) is well known to every student of statistics. However, in the context of locating sampling units in space, simple random sampling can be inefficient, in the sense that other methods for spatially locating sampling units can yield the same or better accuracy with smaller sample sizes. These include stratified random sampling (where spatial strata are identified before the sample units are located), post-stratified samples (where the stratification is applied after the sample has been collected), and systematic sampling (where sample units are located on a regular lattice, but with the lattice randomly positioned in space). Compared to simple random sampling, these methods seek to locate samples more representatively across space, and work most effectively when there is spatial variability in the underlying variable being measured. Statistical estimators for these alternative designs are readily available in standard statistical texts (e.g. Cochran, 1977), noting that the EXP estimator is usually applied to systematic designs, even though it is known the resulting variance estimate may be slightly over-estimated.

The EXP estimator is described below. Importantly, the EXP estimator (and those for the other design-based sampling designs) cannot generate biomass maps from the reference data on their own (Figure 4.3A), although when combined with auxiliary data as part of a design-based model-assisted estimator, biomass maps can be constructed (Figure 4.3B).

A simple illustration of the EXP estimator is where plot-level biomass ( $\text{t ha}^{-1}$ ) is measured at  $n$  locations that are located at random within a region. In this case the mean biomass density estimate for the region as a whole is given by

$$\hat{\mu}^{EXP} = \frac{1}{n} \sum_{i=1}^n y_i \quad (1)$$

and the variance of that estimate as

$$\widehat{Var}(\hat{\mu}^{EXP}) = \frac{1}{n \cdot (n - 1)} \sum_{i=1}^n (y_i - \hat{\mu}^{EXP})^2. \quad (2)^2$$

Here  $y_i$  denotes the estimate for the  $i^{\text{th}}$  sample plot.

---

<sup>2</sup> Equation 2 excludes the ‘finite population correction factor’  $(1 - f)$ , where  $f$  is the fraction of the total population that is included in the sample (Cochran, 1977), as in most biomass mapping analyses  $f$  is small and typically close to zero.

## A. Design-Based

## B. Design-based, model-assisted difference

## C. Model-based

## D. Hybrid

**Figure 4.3 Illustration of the inference methods discussed in the text for estimating biomass and its uncertainty.** (A) Design-based. (B) Design-based model-assisted difference. (C) Model-based and (D) Hybrid of design-based and model-based. The data points in the predictive biomass model represent the biomass estimate from the reference data (y-axis) and the auxiliary data value for the same location (x-axis).

A related estimator is the model-assisted, generalised regression (GREG), that has an adjustment for estimated bias as per Equation (3). The variance estimator has been expressed as

$$\widehat{Var}(\hat{\mu}^{GREG}) = \frac{1}{n \cdot (n - 1)} \sum_{i=1}^n \left( (\hat{y}_i - y_i) - \underline{\varepsilon} \right)^2 \quad (6a)$$

by Cochran (1977, Section 7.4) and in a form similar to

$$\widehat{Var}(\hat{\mu}^{GREG}) = \frac{1}{n \cdot (n - 1)} \sum_{i=1}^n (\hat{y}_i - y_i)^2 \quad (6b)$$

by Mandallaz (2007). For linear models,  $\underline{\varepsilon} = 0$  and for many other prediction techniques  $\underline{\varepsilon}$  will be close to zero for linear regression models so that there will be only small difference in variance estimates in which case  $\widehat{Var}(\hat{\mu}^{MA}) = \widehat{Var}(\hat{\mu}^{GREG})$ .

The advantages of the designed-based estimators are that (i) they are unbiased or at worst asymptotically unbiased, which arises from the probabilistic nature of the sample; (ii) they are relatively straightforward to apply; and (iii) when auxiliary data are available maps of biomass can be produced. The disadvantages are that (i) implementing large-scale design-based monitoring programs with sufficient numbers of reference sample locations can be costly to set up and maintain; (ii) fulfilling the requirement that reference data biomass estimates are made with negligible error can be prohibitively expensive and/or impractical. To achieve this either requires destructive harvesting and weighing at a large number of locations, the development of allometric models of sufficient accuracy that their prediction uncertainty is negligible (Section 2.2), or more operational terrestrial lidar-based estimates (Section 2.3). Often these conditions cannot easily be met; and (iii) whilst biomass maps are constructed from the process, as presented above, there are no corresponding maps of biomass uncertainty, which would otherwise allow sub-regional (e.g. pixel-level) estimates of both biomass and uncertainty to be reported.

## 4.2.2 Model-based estimators

Design-based inference methods require a probability sample of reference data on which to base the inference. This contrasts with model-based estimators, where non-probabilistic reference data, e.g. collected on an ad-hoc basis, can be validly used. In this case, the validity of the inference rests on the correct specification of the model, though model-based inference can also be based on data collected from a probability sample (Figure 4.2), which is advantageous as it

likely increases the model application, and decreases the likelihood that the model will produce estimates with systematic error. In common with design-based inference, the reference data should be estimated with negligible error.

A simple example is where plot-level biomass ( $\text{t ha}^{-1}$ ) is measured at multiple locations, but where those plots do not represent a probability sample, e.g. they were subjectively located, located within easy reach of roads, etc. If additional predictor variables at those locations are available (e.g. elevation, soil type, canopy structure indices from lidar, etc.) then a predictive biomass model can be fit to the data, as described for the design-based model-assisted difference estimator. If the predictor variables exist as spatial information, such as remote sensing datasets, then once calibrated with the reference data the model can be applied spatially to construct a map of biomass (Figure 4.3C).

Although the design-based model-assisted difference estimator and the model-based estimator may use the same predictive biomass model, there are important differences in the way the model is used, in the assumptions underlying the model fitting, and most importantly in the estimation of biomass and its uncertainty.

With model-based inference, a population or sample unit observation is expressed as

$$y_i = \mu_i + \varepsilon_i \quad (7)$$

where  $i$  indexes the sampling units,  $\mu_i$  is the mean of the distribution of possible observations for the  $i^{\text{th}}$  unit, and  $\varepsilon_i$  is the deviation between the observation for the  $i^{\text{th}}$  population unit and its mean. Note this is fundamentally different from the design-based paradigm, that assumes the  $y_i$  are known with certainty, and hence are described by one and only one value.

A regression model or a non-parametric technique such as random forest can be used to predict the population unit mean as

$$\hat{\mu}_i = f(X_i; \hat{\beta}) \quad (8)$$

where  $i$  indexes the population units,  $\mathbf{X}_i$  is a vector of predictor variable observations,  $\mathbf{B}$  is a vector of parameters to be estimated or selected, and  $f(X_i; B)$  denotes the relationship between the predictor variables and the parameters. The model-based (MB) estimator of the population mean is then simply the mean over all  $N$  map units

$$\hat{\mu}^{MB} = \frac{1}{N} \sum_{i=1}^N \hat{\mu}_i^{MB} \quad (9)$$

where  $\hat{\mu}_i^{MB}$  is the model prediction at location  $i$ . An additional key difference between design-based and model-based inference is that, unlike design-based estimators, the MB estimator of the mean cannot be guaranteed to be unbiased. This places additional responsibilities on the map maker to undertake additional validation checks to ensure that the model is fit for purpose. This can be achieved by comparison of the model predictions with independent data not used in the original model fitting (e.g. Roxburgh et al., 2019), or through checks to ensure the model shows no systematic lack of fit to the sample data, and that the range of values in the auxiliary

data is similar in the sample as in the population, thereby supporting the contention that the sample data are representative. As indicated in Figure 4.2, it is also possible to apply an existing model-based estimator to a novel area that lacks reference data. In this case extra care is required in the validation step to ensure that the novel area is consistent with that from where the model was developed (e.g. in close proximity, or with similar species composition and forest structure, etc.).

The model-based estimator of the uncertainty is expressed as a mean squared error (MSE) rather than a variance due to the fact that the estimator may be biased. The uncertainty can be approximated analytically using a relatively complex term that involves components of variability that capture sampling error, residual error, and spatial covariance.

The term that captures the effects of sampling variability on model parameter estimates and model predictions (pre) is denoted

$$\widehat{MSE}_{pre}^{MB} = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1, j \neq i}^N Cov(\hat{\mu}_i^{MB}, \hat{\mu}_j^{MB}). \quad (10)$$

Recalling that  $\hat{\mu}_i^{MB}$  represents the mean of a distribution of possible values for map location  $i$ ,  $\widehat{MSE}_{pre}^{MB}$  therefore quantifies the mean degree of relatedness between all possible pairs of map locations, and takes account of the fact that the model predictions at each point are based on the same sample data, hence the model predictions are correlated.

The residual (res) error term is given by

$$\widehat{MSE}_{res}^{MB} = \frac{1}{N} \sum_{i=1}^N \hat{\sigma}_i^2 \quad (11)$$

where  $\hat{\sigma}_i^2 = Var(\hat{\epsilon}_i)$ , the model residual variance corresponding to the observation of sample unit  $i$ .

The third and final term quantifies the spatial correlation among the residuals (spa), and is necessary as biomass, along with most ecological and environmental variables, is not distributed randomly in space but rather is spatially autocorrelated; in general, values of variables tend to be more similar to those in adjacent locations than with more distant ones. The term is given by

$$\widehat{MSE}_{spa}^{MB} = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1, j \neq i}^N Cov(\hat{\epsilon}_i, \hat{\epsilon}_j), \quad (12)$$

where  $Cov(\hat{\epsilon}_i, \hat{\epsilon}_j)$  is the spatial correlation among the residuals, but is perhaps more readily interpreted as the product of the correlation between  $\hat{\epsilon}_i$  and  $\hat{\epsilon}_j$ , and the residual standard deviations for each location:  $Cov(\hat{\epsilon}_i, \hat{\epsilon}_j) = \hat{\sigma}_i \cdot \hat{\sigma}_j \cdot \hat{\rho}_{ij}$ .

The total model-based error term (tot) is therefore given by

$$\widehat{MSE}_{tot}^{MB} = \widehat{MSE}_{pre}^{MB} + \widehat{MSE}_{res}^{MB} + \widehat{MSE}_{spa}^{MB} \quad (13)$$

Equations 10–13 provide the generic recipe for calculating model-based uncertainty. The details for calculating the  $\overline{MSE}_{pre}^{MB}$  term will vary by the type of model fitted. For regression models  $Cov(\hat{\mu}_i^{MB}, \hat{\mu}_j^{MB})$  can be approximated analytically from the regression fits statistics.

The advantages of model-based inference are (i) the method can utilise data not collected as part of a probability-based sample design, hence can be used in areas where data is sparse and/or where data collection is difficult or impossible; (ii) with careful validation a model developed in one region may be successfully applied in a region that does not have sufficient reference data from which to build a novel model; and (iii) the method can produce both maps of biomass, as well as maps of biomass uncertainty at the resolution of the auxiliary data.

The disadvantages of model-based inference are (i) as with design-based inference, the reference data must have negligible error; (ii) there is no guarantee that the estimator of the mean will be unbiased, requiring additional validation steps to check for possible bias; and (iii) the calculation of the uncertainty term can become computationally unwieldy, and not all of the required information may be available from the auxiliary data on which to calculate all of the MSE terms.

### 4.2.3 Hybrid estimators

Under both design- and model-based inference there is a requirement that the reference data have zero or negligible uncertainty; however the reference data on which biomass maps are often constructed are field-based estimates of biomass, which almost always have non-negligible uncertainty arising from a range of measurement and model errors, and through natural variability (Chapter 2, Table 4.1a).

One solution for dealing with imperfect reference data is a hybrid inference method that combines elements of both design-based and model-based inference (Corona et al., 2014; Fattorini, 2012; McRoberts et al., 2016; Ståhl et al., 2016)(Figure 4.3D). McRoberts et al. (2016) outlines the key features of hybrid inference: (1) a probability sample of auxiliary data such as remotely sensed data or tree-level observations of diameter and height, (2) a model or other technique using the auxiliary data to predict the response variable such as plot-level biomass for the sample units, (3) a design-based estimator of the population mean using the sample unit predictions as if they are error-free, and (4) a combination of design-based and model-based inferential methods to estimate the uncertainty of the estimate of the population mean. For simple random sampling the estimator is therefore

$$\hat{\mu}^{HYB} = \frac{1}{n} \sum_{i=1}^n \hat{y}_i \quad (17)$$

where  $n$  are the number of reference samples, and  $\hat{y}_i$  is the mean plot biomass.

The estimator for the uncertainty additively combines the design-based and model-based components

$$\widehat{MSE}(\hat{\mu}^{HYB}) = \widehat{MSE}^{DB}(\hat{\mu}^{HYB}) + \widehat{MSE}_{tot}^{MB}(\hat{\mu}^{HYB}) \quad (18)$$

Under simple random sampling, the design-based term for the uncertainty is

$$\widehat{MSE}^{DB}(\hat{\mu}^{HYB}) = \frac{1}{n \cdot (n - 1)} \sum_{i=1}^n (\hat{y}_i - \hat{\mu}^{HYB})^2 \quad (19)$$

and the model-based term is that given in Equation (13), noting that the summations in Equations (10 – 12) for hybrid inference are over the total number of map units (N), and not the number of observed sample points (n).

#### 4.2.4 Error propagation by Monte Carlo simulation

Some of the error sources involved in the propagation of errors for estimating biomass uncertainty can be calculated analytically (See box 4.1), but for clarity and simplicity a generic Monte Carlo procedure to propagate uncertainty from all sources is described below. Monte Carlo methods for propagating uncertainty are also necessary for many of the error terms in Tables 4.1a and 4.1b, particularly measurement errors. Monte Carlo propagation of uncertainty is also the recommended method by the IPCC (IPCC, 2000, 2006).

The Monte Carlo example is based on the following assumptions:

- For any observations that are known to be measured with systematic error, and that error has been estimated, then the required correction for estimated bias has been applied to the measurement value prior to error propagation analysis. E.g. for a measurement X that is known to have an error of Y, then the error correction (X') is calculated as X' = X – Y.
- The reference data are calculated from forest inventory sample plot data, and are based on a probability sample – here assumed to be a simple random sample (or a systematic sample treated using the EXP estimators).
- Allometric models are used to convert the field measurement data to biomass, yielding plot-level biomass estimates. These reference data are assumed to be 'imperfect', in the sense that plot biomass has non-negligible uncertainty arising from the sources described in Table 4.1a.
- Auxiliary data in the form of remotely sensed information, e.g. a raster, are available on which a predictive biomass model can be constructed, with the model calibrated to the reference data. Uncertainty of model predictions at a given point is a combination of the model fit errors (Sources E1 and E2, Table 4.1b), model prediction errors (Source E3, Table 4.1b), and additionally embeds the uncertainty in the reference data. The procedure described therefore represents a form of hybrid inference.
- The predictive biomass model is applied to all map units (e.g. pixels), to yield a map of modelled biomass.

<p>Box 4.1</p> <p>Step 1 - allometric model development</p> <p>Two alternative options are provided, depending on whether information on measurement errors is available</p>		<p>Error Source from Table 4.1a &amp; 4.1b</p>
<p><i>Either Option 1 - Including measurement errors</i></p>		
<p>Step 1a.</p>	<p>1a.1. <i>For models predicting dry mass, and where moisture content correction uncertainties are known</i></p> <p>For each required allometric model, and for each individual within the model on which the model is being developed, select from the required probability distribution a value for the moisture content correction factor (MC) to be applied to that individual. Note: the same moisture content factor is typically applied to multiple individuals, and this needs to be recognised in the Monte Carlo procedure to preserve this source of covariance.</p> <p>If there is uncertainty in the fresh mass weights (e.g. through instrument errors, then select a fresh mass for this individual from the required probability distribution.</p> <p>Calculate the individual dry mass as fresh mass x MC.</p> <p>1a.2. <i>For models predicting volume, or for models predicting dry mass and where moisture content correction uncertainties are unknown</i></p> <p>Select the dependent variable directly from the required probability distribution.</p>	<p>A.1.</p>
<p>Step 1b.</p>	<p>For each individual, draw from the appropriate probability distributions values for the independent variables (e.g. stem diameter, height, etc.).</p>	<p>A.2.</p>
<p>Step 1c.</p>	<p>Fit the allometric model(s) to the selected dependent and independent variables from Steps 1a and 1b.</p> <p>For each required allometric model, draw model parameter values at random from the model's parameter variance-covariance matrix, typically assuming a multi-normal distribution, thus ensuring correlations among parameter values are respected.</p> <p>GOTO Step 2.</p>	<p>A.3.</p>
<p><i>Or Option 2 – Excluding measurement errors</i></p>		
<p>Step 1a'.</p>	<p>For each required allometric model, draw model parameter values at random from the model's parameter variance-covariance matrix, typically assuming a multi-normal distribution. Thus ensuring correlations among parameter values are respected.</p> <p>GOTO Step 2.</p>	<p>A.3.</p>

Step 2. Reference data (= plot-level biomass)		Error Source from Tables 1a & 1b
Step 2a.	For each individual within each sample plot, draw from the appropriate probability distributions values for the independent variables (e.g. stem diameter, height, etc.).	B.1.
Step 2b.	For each individual within each sample plot, and at the current values for the independent variables (from Step 2a), select a value for allometric model predicted biomass for each individual from a normal distribution centred on the model prediction value, and with a standard deviation based on the model's prediction (residual) error, and taking note to apply appropriate bias correction if moving from a transformed scale to a natural scale.  For simple linear regression the prediction error is given by: $s_e(1 + A_i^T(X^T X)^{-1}A_i)^{0.5}$ Where $s_e$ is the regression standard error, $X$ is an $n \times (m + 1)$ matrix containing the predictors for each of the $n$ individuals on which the allometric model was fitted, and $A_i$ is a $m + 1$ vector of the independent variables for the new individual $i$ (Chatterjee & Hadi 2012).	B.2.
Step 2c.	If the allometric model-predicted quantity is tree volume (requiring multiplication of AGB by wood density), or if predicted dry mass is to be reported in units of carbon (requiring multiplication of AGB by tissue carbon fraction), then select values for wood density (and/or carbon fraction) from the appropriate probability distribution. Note: a single randomly selected value for either variable should be applied to all individuals that are being estimated by the same allometric model, to retain the covariance.	B.3.
Step 3. Plot-level biomass		Error Source from Tables 1a & 1b
Step 3a.	Sum the biomass for all individuals within all $n$ plots to give $[B_1^{ref}, B_2^{ref}, B_3^{ref}, \dots, B_n^{ref}]$ , i.e. a list of predicted biomass for each sample plot, where 'ref' denotes they are reference data predictions.  If expressing plot-level data as a biomass density (e.g. t AGB ha <sup>-1</sup> ) then for each survey plot, draw from the appropriate probability distribution a value for the plot area, reflecting uncertainty in plot area due to e.g. errors in locating plot boundaries, etc.  Divide the total plot biomass ( $[B_1^{ref}, B_2^{ref}, B_3^{ref}, \dots, B_n^{ref}]$ ) by the plot areas to yield plot-level biomass on a per-area basis $[B_1^{ref'}, B_2^{ref'}, B_3^{ref'}, \dots, B_n^{ref'}]$ , and save for later analysis.	C.1.
<p><b>Repeat Steps 1a – 3a nRep replicate times, to give nRep sets of biomass predictions for each plot. The reference data biomass estimates for the <math>n</math> plots, for the <math>k = 1..nRep</math> replicates, can therefore be given by <math>[B_{1,k}^{ref'}, B_{2,k}^{ref'}, B_{3,k}^{ref'}, \dots, B_{n,k}^{ref'}]</math></b></p>		

Step 4. Predictive biomass model - Development		Error Source from Tables 1a & 1b
Step 4a.	If there is error in the auxiliary data on which the predictive biomass model is to be based, then generate nRep random realisations of the data, through drawing from appropriate probability distributions relevant to that data. Typically, the auxiliary data will comprise spatial GIS layers, or other spatial information, hence care may be required to ensure the spatial autocorrelation in randomly generated layers is conserved.	E.1.
Step 4b.	For each of the k = 1..nRep replicates fit a predictive biomass model to the data, using the auxiliary data from 4a as the independent variables(s), and $[B_{1,k}^{ref'}, B_{2,k}^{ref'}, B_{3,k}^{ref'}, \dots, B_{n,k}^{ref'}]$ as the dependent variable.	-

Step 5. Predictive biomass model - Use		Error Source from Tables 1a & 1b
Step 5a.	For each of the nRep predictive biomass models, select model parameter values at random from the predictive biomass model's parameter variance-covariance matrix, as per Step 1.b' of the allometric model analysis. If the model form is other than regression, then drawing parameter values may require other methods, such as bootstrapped re-sampling or other non-parametric techniques.	E.2.
Step 5b.	<p>Following a similar approach to Step 2b for allometric model prediction error, for each of the nRep predictive biomass models, and for all i = 1..N map units (including the n plot locations), select a value of predicted biomass from a normal distribution centred on the model prediction, using the auxiliary data from Step 4a as the independent variables, and with a standard deviation based on the model's prediction (residual) error, to give for plot i in replicate k.</p> <p>For each of the k = 1..nRep replicates calculate the mean biomass per unit area using the GREG estimator (Equation (3)):</p> $\hat{\mu}_k^{GREG} = \frac{1}{N} \sum_{i=1}^N B_{i,k}^{prel} - \underline{\varepsilon}$ <p>Where <math>B_{i,k}^{prel}</math> is the predicted biomass for the i<sup>th</sup> map unit for the k<sup>th</sup> replicate, and</p> $\underline{\varepsilon} = \frac{1}{n} \sum_{j=1}^n (B_{j,k}^{prel} - B_{j,k}^{ref'})$ <p>with <math>B_{j,k}^{ref'}</math> and <math>B_{j,k}^{prel}</math> being the plot biomass for the k<sup>th</sup> replicate from Step 3a, and the model prediction of that biomass, respectively.</p> <p>The variance of the mean is calculated using Equation (6)</p> $\widehat{Var}(\hat{\mu}_k^{GREG}) = \frac{1}{n \cdot (n-1)} \sum_{i=1}^n ((B_{i,k}^{prel} - B_{i,k}^{ref'}) - \underline{\varepsilon})^2$ <p>Save <math>\hat{\mu}_k^{GREG}</math> and <math>\widehat{Var}(\hat{\mu}_k^{GREG})</math> for later analysis.</p> <p>For each of the i = 1..N map units (e.g. polygons, pixels) calculate the bias-adjusted predicted biomass for that location, , and save the predicted biomass map for later analysis.</p>	E.3.

Following Rubin (1987) and McRoberts et al. (2016), the population (i.e. whole map) mean biomass density can be calculated as:

$$\hat{\mu} = \frac{1}{nRep} \sum_{k=1}^{nRep} \hat{\mu}_k^{GREG}, \quad (20)$$

and the variance of that estimate as

$$\widehat{var}(\hat{\mu}) = \left(1 + \frac{1}{nRep}\right) \cdot W_1 + W_2 \quad (21)$$

where  $W_1$  is the between-replicate variance in predicted mean biomass, capturing the net effects of the various uncertainty sources that were included at each step in the calculation, and is given by

$$W_1 = \frac{1}{nRep - 1} \sum_{k=1}^{nRep} (\hat{\mu}_k^{GREG} - \hat{\mu})^2 \quad (22)$$

and where  $W_2$  is the mean within-replicate variance, given by

$$W_2 = \frac{1}{nRep} \sum_{k=1}^{nRep} \widehat{var}(\hat{\mu}_k^{GREG}) \quad (23)$$

If the total absolute biomass of the region ( $\hat{B}$ ) is required it can simply be estimated as the estimate of mean biomass density multiplied by the total area,  $A$ .

$$\hat{B} = \hat{\mu} \cdot A \quad (24)$$

with the variance scaled accordingly

$$\widehat{Var}(\hat{B}) = \widehat{var}(\hat{\mu}) \cdot A^2. \quad (25)$$

If the total area  $A$  is known to be uncertain, with an error variance of  $\widehat{var}(A)$ , then  $\widehat{Var}(\hat{B})$  can alternatively be calculated via Goodman (1960). This corresponds to error source F.1. in Table 4.1b.

$$\widehat{Var}(\hat{B}) = \widehat{var}(\hat{\mu}) \cdot A^2 + \widehat{Var}(A) \cdot \hat{\mu}^2 + \sqrt{\widehat{var}(\hat{\mu})} \cdot \sqrt{\widehat{var}(A)} \quad (26)$$

Finally, the biomass map for the region can be created by calculating the mean model-predicted biomass across the  $k$  replicates of the analysis. For each map unit  $z$  (e.g. pixels) the biomass is:

$$\hat{\mu}_z = \frac{1}{nRep} \sum_{k=1}^{nRep} B_{z,k}^{pre'} \quad (27)$$

with an estimate of the variability of any given map unit  $z$  given by

$$\widehat{var}(\hat{\mu}_z) = \frac{1}{nRep \cdot (nRep - 1)} \sum_{k=1}^{nRep} (\hat{\mu}_z - B_{z,k}^{pre'})^2. \quad (28)$$

A 95% confidence interval for the regional biomass is thus  $\hat{B} \pm t_{0.95} \cdot \sqrt{\widehat{Var}(\hat{B})}$

### 4.3 Summary

In this chapter three broad inference methods for estimating biomass and its uncertainty from field-based data and for constructing maps of biomass from auxiliary spatial data were described. With traditional *design-based* inference only total regional biomass can be estimated, with no information available on the patterns of sub-regional (e.g. pixel-level) variability; thus on its own traditional design-based inference is of little utility for creating maps of biomass. An extension of traditional design-based inference, *design-based, model assisted* inference combines spatially-explicit (i.e. spatially continuous, georeferenced) auxiliary data with the sampled (reference) biomass data in a predictive model to allow a biomass map to be created. In both design-based variants the validity of the estimate rests upon the validity of the probability sample. *Model-based* inference is superficially similar to *design-based, model assisted* inference, in that a predictive biomass model is constructed from a relationship between sampled biomass and auxiliary data and used to generate a biomass map, but there are fundamental differences. Under model-based inference the sample need not be probability-based, and the validity of the estimate rests solely upon the validity of the fitted model, not the validity of the sampling design. In model-based inference uncertainty is estimated quite differently from design-based inference and is based on the characteristics of the fitted model, with an underlying assumption that the population values are inherently variable (as opposed to design-based methods where it assumed the population values can assume only a single value).

Both design-based and model-based inference requires the reference data to be known with negligible uncertainty, which is almost never the case when plot-level biomass data are calculated using allometric models that are themselves subject to uncertainty. In this situation *hybrid* inference can be applied when there is non-negligible uncertainty in the reference data, and that data is collected as part of a probability sample. In this case design-based inference (which captures the effects of sampling variability) is combined with model-based inference (which captures the uncertainty in the reference data). In general, the auxiliary data on which predictive biomass models are based can be multi-dimensional, and the predictive model can include traditional linear and non-linear regression, or alternative methods such as non-parametric or machine learning techniques. A decision tree is provided (Figure 4.2) that allows users to select the correct inference method that should be used, based on basic knowledge of the user's available data, in addition to the fundamental equations for calculating biomass and its uncertainty under each of the three inference methods. Regardless of the inference method used, care must be taken to ensure any spatial autocorrelation is appropriately accounted for in the analysis, in order to ensure statistical independence. Failure to do so inflates the goodness of fit of the predictive models, leading to over-confidence in model performance.

A total of thirteen possible sources of error were identified, spanning the breadth of calculation steps from initial construction of allometric models through to the calculation of final map biomass and its uncertainty. A generalised Monte Carlo procedure is described to illustrate how

these error sources can be combined or ‘propagated’ through the stages of biomass map creation. Because the procedure incorporates both design-based and model-based elements, and there is an assumption that the reference data are subject to uncertainty, this example falls within the class of hybrid inference. Whilst the procedure is comprehensive, in that it accommodates all thirteen of the identified error sources, there is scope, and indeed perhaps a need, to tailor the algorithm for each particular circumstance. In particular, information on some of the uncertainty sources may not be commonly available (such as those associated with the development of allometric models, where often only summary statistics such as parameter estimates, the regression residual error and sometimes the parameter covariance matrix might be the only information available). In such situations there is little choice but to assume those error sources are negligible, and exclude them from analysis. To recognise this, the described Monte Carlo procedure provides two options, one with a workflow that includes measurement errors during allometric model development, and one that includes only allometric model parameter uncertainty.

Whilst the classification of inference methods into design-based, model-based and hybrid is convenient and fits most situations, these categories are fuzzy at the edges. For example, when conducting analyses by Monte Carlo simulation there is scope to adjust the procedure to suit the desired need. A simple example is a design-based survey with reference data that have a known and quantified uncertainty. In a Monte Carlo simulation it is possible to create replicate reference datasets incorporating that uncertainty (such as done at Step 3a above), and to then calculate appropriate uncertainty metrics based on design-based estimators. However, such an analysis is neither pure design-based, as the reference data are imperfect, nor is it model-assisted or model-based, as no ancillary data were used and no predictive biomass model was developed. This flexibility in the way Monte Carlo simulations can be formulated is also evident in the procedure described above, where the analysis is hybrid in nature, but the GREG estimator is used rather than the relatively more complex model-based estimator.

## 4.4 Recommendations

**It is recommended** where possible and practicable that both measurement and allometric model errors be propagated to estimate field plot AGB with associated uncertainties both in the development of remote sensing biomass products, and in their independent validation. Further, while we acknowledge that some flexibility in the selection of inference methodology is necessary considering the breadth of forest inventory sampling approaches that we anticipate will be used for product development (and even validation), **it is generally recommended** to use hybrid inference for biomass products. This is because it does not assume negligible errors in reference datasets, which is almost never true for biomass. We also endorse the use of Monte Carlo approaches for error propagation, as they have the flexibility to account for differences in field and remote sensing datasets, and different flavours of empirical modeling.

# Chapter 5: Considerations for the Utility of Protocol

There are a wide range of potential users of biomass products that have different product needs in terms of spatial and temporal resolution, uncertainty requirements, and validation plans. This chapter summarizes the primary anticipated user types, written by researchers from three communities, in an attempt to summarize community-specific considerations of these groups. Section 5.1 focuses on the modeling community, 5.2 focuses on policy applications, and 5.3 focuses on scientists interested in non-forest biomass. This Chapter focuses on recommendations for producers of biomass products rather than product users, and hopes to inform the next generation of remote sensing products as to the needs of the wide and disparate user communities.

## 5.1 Utility of protocol by modeling communities

Mathew Williams, Natasha MacBean, Martin De Kauwe

### 5.1.1 Model types

A variety of process models could benefit from interacting with and extracting value from biomass data products. These models range in complexity from intermediate complexity ecosystem C cycle (C-pool) models; through to more complex forest cohort/age-class models; to highly resolved forest gap/individual based models (IBMs). All these model types typically simulate half-hourly to daily dynamics, driven by meteorology and other external factors such as fire disturbance or management interventions. Key differences among models are:

- (i) C-pool models resolve the biogeochemistry of photosynthesis, C allocation to live C pools and their C turnover, representing biomass as the bulk mass of all live C pools. These models operate at a defined pixel scale, that might vary from 1 ha to 1<sup>9</sup> depending on the application, and are typically parameterised for plant functional types (D. B. Clark et al., 2011).
- (ii) Cohort models track biogeochemical fluxes as above but include more detail on the distribution of biomass among trees of different ages or sizes. Thus, these models can resolve differences between plantations and naturally regenerated forests and can predict forest height. These models have similar spatial scale flexibility to C-pool models but to date, are typically run at site, or sub-continental scales (Moorcroft et al., 2001).
- (iii) Gap models, or IBMs, model populations of multiple individual stems within a forest patch scale (<1 ha). The model simulates individual stems of varying species competing for resources (predominantly light), resolving the shifting steady state of natural forests at the scale of canopy dominant stems, with stochastic mortality. From summing individual stem dynamics the biomass at patch scale, and patch stem height, are determined (Ryan & Williams, 2011).

These models are generally used for different purposes. C-pool models are the focus for carbon cycle analyses. They are typically used within Earth System Models (ESMs) to represent terrestrial C cycling and water/energy flow. Model parameters are generally assigned from fixed 'plant functional types'; competition can be determined from comparing simulated growth between different PFTs. Cohort models can simulate C dynamics with more complexity around processes of growth and mortality and include the potential for simulating successional processes. Some ESMs are now beginning to include cohort modelling, but none are operational as part of the latest Coupled Model Intercomparison Project (Jones et al., 2016). Gap-models are high resolution simulators to explore ecological processes and interactions at fine scale (<100 m). They are not currently suitable for regional or global analyses due to the computational costs.

The allocation of carbon to different plant tissues, and the timescale for turnover of these tissues, remain key uncertainties in vegetation modelling and projections of the terrestrial carbon sink (Friend et al., 2014). The processes of respiration, allocation and turnover are afforded simple, largely empirical representations based on limited field studies, contrasting with the complexity in which a key process such as photosynthesis is represented. Most models represent net primary production as the outcome of the difference between photosynthesis and autotrophic respiration. However, recent experimental and observational studies highlight a lack of correlation between photosynthesis and growth, which points to a more complex control on plant production, including C storage pools within plants (Richardson et al., 2013; Rowland et al., 2014). The processes controlling autotrophic respiration are also poorly understood, from plant to ecosystem scales, compared to photosynthesis (Thomas et al., 2019). Accurate and repeated estimates of biomass are likely to refine knowledge of the processes of growth and mortality of plant biomass and their variation across biomes, particularly when combined with other information, such as rates of photosynthesis.

Forest biomass is a dynamic outcome of biological processes of growth and mortality, and exogenous disturbance effects, both natural and anthropogenic. There are enormous challenges to modelling mortality and disturbance as these processes are stochastic, and hard to observe (McDowell et al., 2013). For instance, we have little information on intrinsic rates of tree mortality across the globe (M. O. Johnson et al., 2016). We lack local information on fire impacts on forest biomass. Forest degradation (partial removal of biomass) is poorly quantified globally. Biomass time series can also provide key information on disturbance effects on forests. At landscape scales these data can resolve the effects of fire, extreme weather or pests and diseases, particularly when linked to other data such as burned area, or spectral monitoring of canopy changes linked to diseases. At fine enough scales (~10 m) biomass time series may even provide insights into natural mortality processes, and the death of large stems.

### 5.1.2 Integrating biomass data into models

To be useful, models need to represent real systems reliably. Reliability is generally ensured through the processes of calibration and independent validation against data with robust error estimates. Some portion of data is used to calibrate model parameters and set initial conditions. Remaining data are used to test model outputs, thereby evaluating model bias and random error. Biomass data are only recently available, and largely in temporally ill-defined maps. Errors in biomass products have not always been clearly defined. Thus, biomass data have not typically been used in the calibration and validation process, which has instead focused on using flux data time series. Biomass data provide a significant opportunity to constrain the internal dynamics of C/biomass models, which have been shown to be key drivers of uncertainty among models in forecasts of terrestrial C cycling. Biomass data can also constrain external forcing on models, particularly related to disturbance processes such as degradation.

Clear metadata are required for data products. Hence, **it is recommended** to distribute observations in a NetCDF format. NetCDF files are self-describing and allow significant metadata to be embedded alongside observations. This format is widely used by global modelling groups and would therefore facilitate the widest possible use. In the medium term it is further **recommended** to undertake an effort to combine biomass observations from different satellite sensors within a remote sensing data assimilation system to produce total aboveground biomass, and its components. These different sensors could resolve different parts of the vegetation - e.g. canopy, branches, trunks - linked to e.g. radar wavelengths. The benefit of this integration would be that a) any assumptions made for retrieval algorithms for individual datasets could be made consistent with each other (e.g. underlying canopy structure, parameter values) and b) that more information (from more observations) could go into the biomass retrieval. The outcome of this combined retrieval should also have a more robust error estimate.

The simplest model-data interaction is biomass validation. Forest models produce time series of biomass or C stock maps. Information on biomass stocks and biomass change can be used for validation of all model types, to test steady-state predictions, and representation of dynamical processes. These data can also be used for setting or constraining initial conditions. To facilitate the validation process, **it is recommended** that biomass products are integrated within community land model benchmarking schemes such as the International Land Model Benchmarking (ILAMB) project (Collier et al., 2018). ILAMB is a software platform used for model evaluation by the land modelling community, and therefore provides a means for the biomass community to interact directly with modellers.

To strengthen the validation process, **it is recommended** that uncertainty metrics are linked to all biomass and height data products. Metadata should explain the nature of the uncertainty estimate and its derivation (e.g. following recommendations in Chapter 4). Clarity is required on the quantification of random error at pixel scale, spatial correlation of random error (i.e. sensitivity of random error to aggregation), and measurement bias at pixel-to-regional scales. Further, the error on biomass and height change estimates (i.e. pixel differences between

successive biomass/height maps) must be clearly specified and included at time of product release. Information on local variability, i.e. biomass uniformity sub-pixel, is also valuable for the modelling process. While this protocol focuses on recommendations for biomass stock product validation, uncertainties on change information are equally important.

Data on height, and height change can validate cohorts and IBMs. Cohort and gap models are increasingly being implemented in ESMs to improve the mechanistic realism of their dynamic vegetation module (DVM) component. DVMs are important as they are used for predicting long time scale changes in species distributions as a result of climate and land cover change. To maximise value for DVM validation **it is recommended that** clarity on the relationship between height and biomass estimates is provided, i.e. whether these measurements are correlated or independent. This information will help to interpret the model-data conformity or mis-match. Information on vertical variability of biomass from tomography (ESA Biomass) could validate height/biomass outputs of cohort models and IBMs. Full waveform lidar estimates of vertical canopy structure – as will be obtained by the forthcoming GEDI mission – will also be useful in this regard. Additionally, canopy structure estimates will be beneficial in parameterizing the multi-canopy layer energy schemes that are currently being implemented in some ESMs.

The geographic coverage and detail required by modellers is dependent on model domain and resolution. Products  $\geq 0.5^\circ$  serve for Earth System Model validation. Products at resolutions of  $\sim 1$  ha serve cohort and gap models for decision support, interaction with local stakeholders, and understanding of fundamental ecological processes. Annual products allow resolution of landscape dynamics, including growth, disturbance and management. Sub-annual products allow resolution of seasonal process variation, for instance growth and phenology. **It is recommended** that annual  $0.5^\circ$  products are provided as a standard for evaluation against global models. The latest CMIP6 simulations are targeting  $1^\circ$  and this resolution fits ILAMB benchmarking. **It is recommended** that the highest resolution products possible are provided with the fewest gaps and for the largest domain possible, to allow more detailed model and process evaluation for regional studies. The mapped domain, if limited spatially, could be decided in consultation with *in situ* biomass researchers, to target study regions linked to product calibration and validation.

### 5.1.3 Model data fusion

Biomass data can also play an important role in model calibration. The calibration process uses biomass maps, and other data such as LAI from satellites, to constrain and calibrate model parameters and minimize model-data mismatch (Exbrayat et al., 2019). Calibration activities require georeferenced data sets with clear error characterization, as outlined above, and so are consistent with our previous recommendations. The production of biomass maps globally has already provided a basis to constrain estimates of wood residence time (Bloom et al., 2016; Forkel et al., 2019). Repeated biomass data evaluated at site scale has been shown to provide constraint on estimates of woody increment, allocation to wood, and on autotrophic respiration (Smallman

et al., 2017). As repeated biomass data become available at high resolution across broader domains there is a clear opportunity to constrain C cycle processes in ecosystem and global C cycle models.

## 5.2 Policy-relevance of protocol

Martin Herold and Sarah Carter

Biomass information including uncertainty estimates are useful for a number of purposes from national to international reporting related to forest change, to monitoring climate variables and sustainability goals, and supporting local actors in implementing improved forest and land use management. They are central to the achievement of international goals and national commitments related to forest conservation and management, climate change, and sustainable development. Most prominently, the Paris Agreement on Climate Change requires that the progress on the implementation of the United Nations Framework Convention on Climate Change (UNFCCC) National Determined Contributions are transparently reported, for which improvements in the quality of national greenhouse gas (GHG) inventories is key. Biomass data are also relevant for Goal 15 of the United Nations (UN) Sustainable Development Goals (SDGs) that aims to promote the implementation of sustainable management of all types of forests, halt deforestation, restore degraded forests and substantially increase afforestation and reforestation globally by 2020.

This diversity of users brings different user requirements in terms of the data needs (including the scope and scale of biomass products), and in terms of considerations on uncertainty (see Table 5.1):

**Table 5.1 Summary of key policy initiatives, user groups and requirements for biomass mapping**  
(Herold et al., 2019)

Policy initiative	Key user groups	Biomass data needs	Considerations on uncertainty
IPCC/GCOS	Global climate data users and global assessments (i.e. IPCC WG 1 and WG3)	<ul style="list-style-type: none"> <li>- Aboveground biomass as one of the Essential Climate Variables (ECV)</li> <li>- Optimal: regular global forest biomass monitoring at 50-100 m resolution at annual intervals</li> <li>- Focus on long-term consistency as input to global and regional climate and vegetation models</li> </ul>	<ul style="list-style-type: none"> <li>- Uncertainty and stability of ECV products are to be assessed and reported for relative and absolute systematic deviation and confidence interval or RMSE, overall and by biomass class/range estimated using reference data of better quality</li> <li>- Coordinated international activities for uncertainty characterization and reference data collection are required</li> </ul>

UNFCCC national reporting, transparency framework and global stocktake	National GHG inventory experts and UNFCCC roster of experts for technical assessments and review	<ul style="list-style-type: none"> <li>- Estimation of carbon emissions and removals from forest changes; also including non-forest areas with significant woody biomass (i.e. agriculture/ grasslands)</li> <li>- Reporting done by countries and all countries need to report regularly (at least a summary of the GHG inventory bi-annually)</li> <li>- Various options of integrating biomass maps in national GHG inventories</li> <li>- Greatest need in tropical countries where availability of plot data and sustainability of NFIs remains an issue</li> <li>- Regular global stocktake by UNFCCC may require data for reconciling country reporting to provide global estimates of progress</li> </ul>	<ul style="list-style-type: none"> <li>- IPCC GPG: estimates should be unbiased (on the national level) and uncertainties reduced as much as practicable</li> <li>- IPCC Tiers: national data needed for Tier 2</li> <li>- Uncertainty estimates required on national estimate</li> <li>- Continuous improvement process as part of national GHG inventories</li> <li>- Need for consistent (global) data sources (including uncertainty characterization) for technical assessment and global stocktake</li> </ul>
REDD+ activities	National REDD+ agencies, forest monitoring experts, REDD+ donors/investors and independent assessment bodies	<ul style="list-style-type: none"> <li>- Estimation of emission factors and forest carbon stock changes for establishing forest reference level and REDD+ results to access result-based finance</li> <li>- Assessment of potential forest mitigation activities</li> <li>- Requirements can vary according to the financial initiative (i.e. GCF, FCPF, bilateral organisations, voluntary markets)</li> <li>- Independent data sources that verification teams can use for comparison</li> </ul>	<ul style="list-style-type: none"> <li>- Uncertainty requirements vary by performance scheme</li> <li>- Consistency, accuracy and transparency needs to be sufficient to be convincing for technical assessments and verification of the results of REDD+ activities</li> <li>- Stepwise improvements possible and encouraged</li> <li>- Discounts in payments due to high uncertainty or conservative adjustments possible</li> </ul>
Sustainable development goals	National statistical office responsible for SDG indicator reporting, UNSD	<ul style="list-style-type: none"> <li>- Biomass changes as one sub-indicator of SDG 15.3.1 but also important input for others that are required for all countries</li> <li>- Detailed requirements are still developing but reporting is to be done by countries on annual basis 2015-2030</li> </ul>	<ul style="list-style-type: none"> <li>- Not yet known but reporting of SDG indicator should allow for the assessment of trends 2015-2030</li> </ul>
(Sustainable) Forest management	National forest institutions, forest industry, certification schemes	<ul style="list-style-type: none"> <li>- Management plans</li> <li>- Forest laws and strategies</li> <li>- Fire prevention plans</li> <li>- Bioenergy plans,</li> </ul>	<ul style="list-style-type: none"> <li>- Emphasis on stand-level/spatially explicit information provision</li> <li>- Quantification and understanding of uncertainties should be incorporated in management decisions</li> </ul>
Stakeholder engagement and transparency	Societal actors and broader set of forest-related stakeholders, including local communities	<ul style="list-style-type: none"> <li>- Free and open biomass data accessible to non-technical stakeholders</li> <li>- Biomass sometimes used for independent assessments, as a simple proxy for forest health, intactness and habitat quality, forest resources assessments, etc.</li> </ul>	<ul style="list-style-type: none"> <li>- Transparent information and uncertainty characterization required by all stakeholder groups</li> <li>- Uncertainty requirements vary by stakeholder group</li> </ul>

A summary of the key initiatives, user groups and requirements for biomass mapping in Table 5.1 emphasizes that biomass data derived from space-based data are useful for a wide range of policy-relevant applications. Uncertainty information is required by all stakeholders interested in using biomass maps (Romijn et al., 2018). This protocol document is described as the first agreed “best practices” document to provide a proper independent uncertainty assessment that should be used for biomass mapping products being generated using space data. **It is recommended** that independent uncertainty assessment as described in this protocol should be treated as a benchmark document that essentially caters to two communities: (1) the data producers that require independent validation to understand the quality of their product and can improve their efforts over time and (2) the user of the product that needs to understand whether to use a certain biomass for a specific purpose and why; including consideration of how uncertainties affect the uptake of the product in a certain application. In that context, it is important to consider that different applications have specific requirements on what they expect from biomass and uncertainty characterization (see Table 5.1) in terms of:

- Geographic scope: which ranges from global scale (i.e. for use in climate and vegetation models) or national level estimates since it is most relevant for country GHG inventories
- Spatial resolution: from spatially-explicit/stand-level information of less than one hectare to multiple kilometres for global vegetation models
- The final biomass estimate needed by the users: can be the total or average biomass per country or forest type or a local (i.e. a forest management unit) /pixel-specific value
- The uncertainty estimates required: which can include relative and absolute systematic deviation (or bias) and confidence interval or RMSE. They can be provided for the overall estimate or by biomass class/range
- Timing: whether a biomass estimate is needed for one time (i.e. one year) or for multiple years. Some users require data that are most recent (near-real time information) or available consistently for longer time series
- Thematic content: users often ask for as one time maps but applications increasingly require biomass change information
- Definition: there is variability in needs in terms of which vegetation compartments are considered (i.e. minimum tree size) and whether dead biomass is included or not
- Compliance with IPCC good practice guidelines: (1) “neither over- nor underestimates so far as can be judged,” and (2) “uncertainties are reduced as far as is practicable” (IPCC, 2006).

All these choices influence the way the biomass map product should be generated and how the uncertainty of the products is to be assessed for the purpose of the different user/policy

requirements (see Section 5.2). This means that one biomass product and uncertainty characterization approach will not work for all users. **It is recommended** that any effort of assessing biomass products should be co-developed by both producers and users. Often user organizations have their own forest and biomass reference data that they would like to integrate with biomass map data. Such efforts are thus, not only aiming at the technical credibility of a biomass map product, but also on creating ownership and saliency that are often most important for ensuring user uptake. For example, an internationally-produced biomass map can only become part of IPCC Tier 2 or Tier 3 national emission estimation if integrated with yield data acquired in the country. It is also often the user alone that can fully judge what implications estimated biomass and uncertainties have on their application. This information can be fed back to the producer on where to improve. So in summary, biomass map production for a specific application is an interactive process of co-creation from both producers and users, and uncertainty assessments are most useful if done in partnership.

## 5.3 Utility of Protocol by non-forest research communities

Natasha MacBean, Oliver Philips, Michael Falkowski, Patrick Jantz, Scott Goetz, Tom Crowther

### 5.3.1 Context

The boundaries – conceptual, spatial, temporal – between ‘forest’ and ‘non-forest’ are complex and often contested by science and society. These boundaries matter. For example the standard FAO definition of forest having 10% tree cover or more (FAO, 2018) results in large areas of dry and semi-arid tropics that are not tree-dominated being classed as forest, and current debate about the global extent of forests in dryland derived from high resolution optical imagery hinges on details of definition (Bastin et al., 2017; Griffith et al., 2017). For the purposes of this overview we adopt as simple an operational definition of forests as possible, as ‘land with largely continuous tree cover’. Most trees which grow *outside* forests thus experience different growing conditions from most growing within them.

Given this, the user base for this Biomass protocol is potentially very wide-ranging and at least three distinct potential communities of “non-forest” user communities can be identified. These include (1) users whose main focus is the state and trajectory of non-forest biomes themselves, as well as (2) forest-oriented users in academic and policy-maker communities who need to understand and quantify biomass dynamics and stocks as a result of land-use change processes that can take land out of forest, and back into forest. A further group of users (3) are focused on tracking carbon stores and fluxes below-ground; while this group is relatively smaller, it represents a chronically under-researched topic, and one which for obvious reasons is particularly challenging for space-based Earth observation to impact.

### 5.3.2 Significance

Each of these communities study systems and processes of major global significance. Thus:

(1) *While non-forests contribute less than 20% of global biomass, they represent half of terrestrial productivity and cover ca. 70% of the Earth's land surface* (Pan et al., 2013). The largest terrestrial tropical biome, the savannas, are traditionally thought of as grass-dominated, yet the 'savanna' concept has proven even harder than that of 'forests' to operationalise consistently across continents (cf. Torello-Raventos et al., 2013). Much vegetation considered by most ecologists as savanna is structurally dominated by trees, with, on average, at least 50% tree cover coexisting with C4 and C3 tropical grasses (Lloyd et al., 2008).

(2) *Approximately 200,000 km<sup>2</sup> of forest is converted each year to non-forest states as a direct result of human activities* (M. C. Hansen et al., 2013). Additionally, elsewhere the planet is gaining tree cover and biomass as a result of successional processes, active planting, and indirect anthropogenic drivers including longer growing seasons (e.g., at the boreal / tundra margin), changing fire regimes, and increasing carbon dioxide (e.g., woody encroachment at the tropical forest / savanna interface) (Mitchard & Flintrop, 2013; Schimel et al., 2015). However the boundaries between "forest" and "non-forest" are defined, it is important to be able to track biomass dynamics across these boundaries in as consistent and unbiased a way as possible.

(3) *Carbon stocks below-ground are easily overlooked, extremely poorly constrained, and yet can exceed aboveground values - and of course are not confined simply to biomass.* For example there are huge but uncertain stores of organic carbon in Congo peatlands (6-46 Pg C, Dargie et al., 2017) and Amazon tree roots (13-26 Pg C, Malhi et al., 2006), while across all savannas most ecosystem carbon is below the surface, in soil and roots (e.g. Scharlemann et al., 2014). Global soil carbon has been estimated in excess of 2,000 Pg in the top 1m of soil, much of that outside of forests (Batjes, 1996). While below-ground stores and processes are largely invisible from space there is a strong need to link below-ground stock and flux measurements with the above-ground focus of most Earth observation and forest inventories.

### **5.3.3 Woodlands, savannas, and grasslands**

If we adopt an operational definition of forests as land with continuous tree cover, then it follows from ecological first principles that non-forest trees will have different allometric relationships than forest trees, for at least three reasons. First, plants growing in non-forests experience less light competition once they exceed the ground layer. The reduced above-ground competition drives different responses to the trade-off between investing in stem height versus lateral growth, resulting in altered ratios of crown:stem biomass investment (cf. e.g. Bonser & Aarssen, 1994 for such plasticity in response to light competition). Likewise, in relatively short, disturbance-affected forests in parts of western Amazonia, crown:stem ratios for large trees are much greater from those in taller rainforests, with consequences for biomass (R. C. Goodman et al., 2014). Second, plants growing in non-forests will be limited more by deficiencies in the availability or seasonality of soil water or nutrients. This implies that different trade-offs exist between investing in growth above-ground and below-ground in forests and open systems, with the consequence of altered (increased) root:shoot ratios. Third, disturbance regimes that

dominate open systems more than forests, notably fire and grazing, also heavily affect the allometry of trees in open ecosystems, helping drive above-ground ontogenetic changes and plastic responses to episodic disturbance (e.g. Archibald & Bond, 2003; Moncrieff et al., 2011), as well as enhanced allocation below-ground. Overall, field estimates of root:shoot ratios of tree-dominated neotropical vegetation summarized by Hoffman et al 2003 range from 1.0-2.9 in savanna, to 0.42–0.84 for dry forests, and as low as 0.1-0.17 in rainforests. Similar large differences apply globally, although savannas remain chronically data-poor in terms of detailed biomass assessments (e.g. Mokany et al., 2006). In short, because forests and non-forests are so different ecologically, allocation of biomass above-and below-ground and to different above-ground compartments, also differs greatly. **It is recommended** that protocols devised to infer tree biomass in forests are evaluated for application to their non-forest equivalents, since it is expected that they will need substantial modification.

Very-high resolution optical observations potentially permit large-scale, highly resolved mapping of large numbers of individual trees. In open systems tree-centric biomass estimation is particularly promising as the scarcity of overlapping crowns reduces confusion, permitting accurate measurement of crown projections (cf. Bastin et al., 2017). By combining field data with crown metrics derived optically (or crown and height metrics from lidar point clouds (whether UAV, airborne, or spaceborne)) it is in principle possible to estimate the diameter and aboveground biomass of remotely sensed trees - if the species of each tree is also known (as identity is the main driver of wood density, which strongly determines AGB). Nevertheless, allometric prediction of biomass from crown - or crown and height - dimensions developed for forest trees (Jucker et al., 2017) entails systematic error if applied to estimate tree biomass outside forests, as allometric relationships differ. Improved estimation of non-forest tree aboveground biomass therefore requires developing bespoke allometric relationships for non-forest trees. **It is recommended** that for aboveground biomass estimates, these bespoke allometric relationships for non-forest trees be generated via a combination of TLS assessment and destructive harvesting. Both methods are needed because TLS can estimate wood volume but not wood density. Wood density, which also controls biomass, varies among-species, within-species, and within-trees.

Regarding uncertainty, woodland biomass products would provide area and biomass estimates that would then be used in conjunction with models and other data to estimate total C stock changes in biomass, dead organic matter (woodland floor, coarse woody debris, etc), and soil C. Uncertainty is generally propagated through inventory calculations, and optimally would be provided as variances or covariances in total biomass C for the spatiotemporal product (covariances in time and space).

### 5.3.4 Management in woodland ecosystems

In the US, most land management agencies with tenure over woodland systems (e.g., Bureau of Land Management, Natural Resources Conservation Service, USFS) are not concerned with changes in biomass or carbon. They are however interested in tracking changes in the spatial

extent and canopy cover in these systems to support grazing and wildlife related management goals. Given the strong linkage between tree cover and extent to biomass in woodland systems, such data products derived from remote sensing could be used to support these goals. The EPA's National Greenhouse Gas Inventory (NGGI) would be a primary end user of biomass or carbon data products in woodland systems in the US (S. Ogle, personal communication, n.d.). Biomass and carbon data products in woodlands could be used to address C stock changes due to woody encroachment, retraction of woodlands, agroforestry and other tree plantings outside of forest lands. Analyses from the US NGGI to local municipal planning would certainly benefit from better data on biomass C in woodlands. In Arizona, the Altar Valley Conservation Alliance is using satellite data to understand effects of prescribed fire on forage availability – biomass estimates would be a useful addition.

The geographic domains and spatial scale required by the NGGI and other rangeland managers would depend on the analyses, but typical national scale analyses for the NGGI evaluate changes from the 1980s through the most recent years (S. Ogle, personal communication, n.d.). An annual time scale is generally the focus of these types of assessments because smaller scale changes such as seasonal or monthly, are not used as the basis for carbon credits. Moreover, longer term changes can be derived from the annual data. Finally, near real-time or seasonal biomass estimates would be useful for ranchers to know where there is forage for their livestock without having to move themselves (or the animals) there first). In California for example, many ranchers use BeefTracker (<http://www.beeftracker.org/>) for this purpose.

### **5.3.5 Soil/belowground biomass**

The soil represents the largest terrestrial repository of carbon in the biosphere, storing ~3 times as much carbon as terrestrial vegetation. As the primary source of most macronutrients that are necessary for plant growth, the soil is critical for regulating aboveground productivity. But the soil also directly contains up to 50% of the plant biomass in most terrestrial ecosystems in the form of roots. In addition, soils also support the largest living and dead components of the organic biomass pools on Earth, as millions of species are responsible for decomposing and processing the dead biomass (primarily plant biomass) entering from the aboveground system. As such, soils form a highly dynamic component of the biosphere and a central component of Earth system dynamics.

The biochemical characteristics of the soil determine various ecosystem services including soil fertility, nutrient cycling and water filtration, while the biophysical characteristics determine soil quality, stability and structure. High-resolution maps of these soil characteristics are therefore critical for guiding targeted land management decisions that are aimed at improving food production, carbon sequestration or city/town planning capabilities. A detailed understanding of the spatial patterns in soil carbon storage is also necessary for scientific efforts to understand the global carbon budget and its influence on the future climate.

One key feature of the soil system is the challenges inherent in mapping soil organic features across space: the soil is opaque. The fact that ecosystem biomass and carbon is not directly visible from above is clearly a significant challenge for the Earth observation age. In particular, most biomass and carbon in non-forest ecosystems is belowground. Root:shoot ratios in these ecosystems are often high, but vary greatly and remain poorly constrained.

To address the challenge of mapping soil organic features across space, geologists and soil scientists have traditionally made use of physical soil sampling and ground penetrating radar approaches to detect a range of soil characteristics including soil depth (Wollschläger et al., 2010), carbon storage (Hruska et al., 1999) or roots (Comas et al., 2017). However, these approaches are time consuming, expensive and spatially restrictive, limiting their applicability across broad spatial scales. As a result, most high-resolution, broad-scale soil mapping efforts have been based on inferences that can be drawn from spectral information and vegetation mapping approaches (J. B. Fisher et al., 2016; Hengl et al., 2014, 2017). Moreover, the soil classes which largely control variation in below-ground carbon (at least soil carbon), are variable at multiple scales and in many tropical regions require higher observation density than currently available for reliable interpolation (e.g. Moulatlet et al., 2017).

The approaches for inferring soil information from satellite data can vary, depending on the characteristics in focus. Some soil information can be inferred directly from observations of the aboveground system. For example, given the well-characterized obligate associations between specific tree taxa and their symbiotic mycorrhizal fungi or nitrogen fixing bacteria, it is possible to estimate information about the soil microbiome based on tree dominance from spectral approximations of plant taxonomic identities (J. B. Fisher et al., 2016). Specifically, nearly all tree species form symbiotic relationships with one of two types of mycorrhizal fungi – arbuscular mycorrhizal) and ectomycorrhizal fungi – so the detection and mapping of mycorrhizal status over large areas can be possible using high-resolution spectral estimates of plant groups (J. B. Fisher et al., 2016). As arbuscular mycorrhizal- and ectomycorrhizal-dominated forests often have distinct nutrient economies, this information can provide valuable insights into fundamental soil processes such as nutrient cycling and fertility (Averill et al., 2014). In addition, root:shoot ratios are well characterized for many tree species. As such, belowground plant biomass can be approximated in many forest communities using information about aboveground biomass in combination with tree taxonomic information (Cao et al., 2014).

Although some soil information can be approximated directly from aboveground vegetation information, the vast majority of belowground information can only be inferred indirectly. Most spatially-explicit information about soil characteristics are generated using globally fitted models using spectral information as covariate data, e.g. SoilGrids (Hengl et al., 2014, 2017), the Harmonized World Soil Database (HWSD; Fischer et al., 2008), or the FAO Global Soil Organic Carbon map (GSOCmap; FAO and ITPS, 2018). “Raw” soil data are also available from the World Soil Information Service (<http://www.isric.org/explore/wosis/accessing-wosis-derived-datasets>). Of all these products, SoilGrids is the most recent and highest resolution product.

Given that plants are primarily responsible for the organic matter inputs to soil, vegetation characteristics can explain a considerable proportion of the soil carbon and nutrient accumulation across landscapes. In addition, plants interact with geological processes and climate conditions to determine soil physicochemical properties. Using this approach, the latest SoilGrids database draws heavily on MODIS 250 m data to generate global maps of most soil physical and chemical characteristics (including organic carbon, pH, texture etc) across multiple depths (up to 2 m deep). This information can provide a valuable tool for linking belowground and aboveground components of the ecosystem, and for predicting the ecological context that might be necessary for shaping plant communities across the globe.

Just as with above-ground carbon, below-ground pools are sensitive to climate-change, to land-use change, and to change in ecosystem productivity. In the twenty-first century the need for large-scale, integrated, multi-technique, long-term, whole ecosystem assessments is stronger than ever. A model for this already exists. Between 1970 and 1985 the Brazilian government set about the daunting task of mapping its remote Amazon and other territories from the point of view of geology, geomorphology, soil, vegetation, and agricultural capacity. This project - Projeto Radar da Amazônia, known since 1975 as Projeto RADAMBRASIL – combined cutting-edge remote-sensing technology of its time (airborne radar) with an extraordinary ground-based effort which included thousands of soil samples and inventory plots across an area of several million km<sup>2</sup>. This led to what are still by far the world's best resource maps for a large tropical territory. Half a century on, the challenge now to the global community has remarkable parallels to that faced by Brazil in 1970 – how can we combine a growing array of new and old technologies in a concerted way to see as precisely as possible, and as deeply as possible?

**It is recommended** that satellite-derived aboveground biomass estimates are checked for consistency with available data on soil properties and belowground carbon storage, including those products listed above such as SoilGrids (Hengl et al., 2014, 2017).

### 5.3.6 Biodiversity

Biodiversity researchers frequently use biomass estimates for improving ecological understanding of how biomass relates to biodiversity and for assessing the potential of ecosystem service co-benefits, where investment in biomass protection or restoration is expected to provide incidental protections or gains for biodiversity (Brancalion et al., 2017; Van de Perre et al., 2018; Venter et al., 2009).

The ecological question of how biodiversity influences biomass focuses on carbon and nutrient cycling by animals and how biomass production, more so than total aboveground biomass stocks, is enhanced and appropriated by herbivores (Duffy et al., 2017; J. Liang et al., 2016). Effectively estimating biomass production from space requires precisely geolocated, repeat measurements of vegetation structure. Such measurements are currently not well quantified using existing spaceborne lidar but are likely to be improved with the next generation of instruments, particularly the GEDI mission. The question of how standing carbon stocks relate to biodiversity

is more tractable from a remote sensing perspective and, with the negotiation of REDD+, has yielded a large volume of studies (reviewed by Goetz et al., 2015; Mulatu et al., 2017). Much of the focus of this literature has been on tropical forest ecosystems because of their contribution to global biodiversity, large aboveground carbon stocks, and high rates of forest conversion to agriculture (Gaston, 2000; Watson et al., 2016).

There is still debate about how biodiversity is related to biomass. We know that old growth forests contain unique species assemblages (Barlow et al., 2007; Watson et al., 2018) and that as regrowing forests accumulate biomass, their species assemblages become more like those found in old growth (Barlow et al., 2007; Letcher & Chazdon, 2009). Because of this, biomass estimates have frequently been used as indicators of forest condition and biodiversity (Bustamante et al., 2016 Figure 1). However, this relationship is likely to result mostly as a consequence of biomass and tree species richness covarying as a result of succession advancing, more than any causal relationship between the two. When forests are studied in detail, it is clear that the biodiversity-AGB association only applies at some scales (Di Marco et al., 2018) or is restricted to a specific range of biomass values (Ferreira et al., 2018).

In tropical forests, it is notable that (1) very high biomass forests can have remarkably low diversity (e.g. monodominant systems in central Africa and southern Brazilian Amazonia, (Marimon et al. 2020)) and (2) the tropical continent with the most species-rich forests (South America) has the lowest per area biomass forests of all (ForestPlots.net, 2020). It is clear too that across all old-growth tropical forests there is no strong association between biomass and tree species richness (Sullivan et al., 2017).

**Figure 5.1. Conceptual model of the relationship between biomass and biodiversity** (from Bustamante et al., 2016). Note that the model does not apply to variation within old-growth forests, where the association between biomass and biodiversity breaks down.

Lasky et al. (2014) reported early successional forest plots average 76.4 mg ha<sup>-1</sup>, mid-successional 116.5 mg ha<sup>-1</sup>, and old-growth 198.3 mg ha<sup>-1</sup>. Similar classes have been used to assess the regrowth potential of secondary forests in the Latin American tropics (Chazdon et al., 2016) and the potential for biodiversity-biomass co-benefits in Colombia (Gilroy et al., 2014). This implies that a precision on the order of 10's of megagrams per hectare could be useful to distinguish age-classes relevant to biodiversity studies and conservation priorities. GEDI is expected to achieve accuracies of 20 Mg/ha (Goetz & Dubayah, 2011), suggesting a level of precision that will be useful for informing biodiversity-carbon studies and related decision-making needs. It is important to note again that the AGB-species richness relationship in the tropics breaks down in old-growth forests. Hence, AGB mapping can be a useful predictor of secondary tropical forest biodiversity, but AGB *per se* tells us little about biodiversity in old-growth systems.

**It is recommended** that satellite-derived aboveground biomass estimates be used for first-order prediction of tropical tree biodiversity, as long as old-growth forests can be first masked out using a reliable independent data source, such as with help of the PRODES product from INPE for Brazilian Amazonia.

The spatial scale at which biomass information is needed for biodiversity assessments varies by application. Biodiversity sampling is time consuming and expensive (Bustamante et al., 2016) and scale sensitivity has been observed in the relationship between biodiversity and biomass (Chisholm et al., 2013). In many cases, establishing many small plots (< 0.1 hectare), may be the most efficient choice for multi-taxa biodiversity surveys, especially in heterogeneous landscapes (Gilroy et al., 2014). For example, once installed, camera trap grids are considerably more cost effective than repeat surveys. However, even one of the most extensive camera trapping efforts, the Tropical Ecology Assessment and Monitoring network, only deployed traps at a density of 1 trap/2 km<sup>2</sup>. Such constraints could lead to scale mismatches between biodiversity observations and remotely sensed biomass estimates. Even so, with appropriate sampling designs, the area represented by biodiversity plots can be large, on the order of several hectares (van der Sande et al., 2017), making comparisons with biomass estimates feasible. For larger payment for ecosystem service projects, such as those envisioned as part of a successful REDD+ strategy, the expected spatial scale of biomass estimates from spaceborne instruments may be commensurate with project needs. In a comprehensive assessment of restoration projects in the Atlantic Forest of Brazil, project size averaged 10 hectares (Brancalion et al., 2018). Finer scale biomass estimates would allow for scaling effects to be explicitly considered, and may be desirable. It is important to recognise that human-impacted tropical forests are often extremely heterogeneous in space because human impacts (deforestation, fire, logging, subsequent use) are also very heterogeneous. This spatial variation adds challenge to the task of matching single and repeat satellite-observations to fine-grained on-the-ground processes.

Temporal scales needed by the biodiversity community also vary by application. Forest clearing results in immediate biomass decreases. In places where land use change occurs rapidly, annual observations would be most effective in documenting such changes. Biomass increases as forests regrow are much more gradual. Estimates of carbon accumulation of ~4 Mg of carbon per hectare

per year in the western Andes (Gilroy et al., 2014) suggest that at expected accuracies of GEDI data products (Dubayah et al., 2020), a minimum of 5-10 years of regrowth would be needed to confidently detect change in biomass. Tropics-wide the average annual rate of AGB increase in tropical forests varies widely, from 3.4 (Asia) to 7.6 (Africa) Mg/ha/yr in younger secondary forests, from 2.3 (North and South America) to 3.5 (Africa) Mg/ha/yr in older secondary forests, and from 0.7 (Asia) to 1.3 (Africa) Mg/ha/yr in old-growth forests (Requena Suarez et al., 2019). Clearly, AGB recovery rates decline with forest age. Performance periods for payment for ecosystem service projects may be anywhere from a few years to 30 years, thus a temporal resolution of 5-10 years may be acceptable and achievable in some forests.

**It is recommended** that satellite-derived aboveground biomass estimates report the uncertainty in (1) absolute values of AGB and associated metrics such as canopy height that are likely to change with forest age, (2) any change over time in these metrics, and (3) the associated footprint area and its precise location. Users will need to know the precise date when each metric was acquired and for estimating biodiversity recovery rates are likely to benefit most from sensors that measure the same location repeatedly over many years.

In summary, several existing biodiversity-biomass applications, especially those operating at scales > 1 ha, may be enhanced by next generation mission observations. Applications that require higher temporal or spatial resolutions than those provided by GEDI will likely need to rely on fusion approaches with planned spaceborne radar systems and/or existing high-resolution optical systems.

# Chapter 6: User-led Validation with pre-existing reference data

Valerio Avitabile, Jean-François Bastin, Sytze de Bruin, Laura Duncanson, Martin Herold, Inge Jonckheere

## 6.1 Introduction

This CEOS protocol has focused on a discussion of ideal good practices for spaceborne aboveground biomass product validation. However, oftentimes there are insufficient funds/resources to collect new data following the recommendations in Chapter 2. Existing and available data may provide reference information for biomass predictions that are not necessarily derived for the purpose of calibrating and validating biomass maps and in this sense are different from the recommendations provided in Chapter 2 and 3. They can be useful as reference data if their quality and characteristics allow for comparison with biomass map predictions (see e.g. Ploton et al., 2020 for an example of valorisation of commercial forest inventories). These data can provide not only a quality assessment for the map producers but are often essential to build trust and support the uptake of maps for certain end users and (local) applications.

Users of biomass maps include national inventory experts, global climate modelers, local climate change mitigation project implementers, sustainable supply chain managers, or environmental watchdog organizations. Each user category has specific needs when it comes to biomass estimation and accuracy requirements with respect to spatial resolution, geographic extent, timing, thematic content and definitions, and type and standards of uncertainty reporting (see chapter 6; Herold et al., 2019). However, such requirements often cannot be assessed without considering additional existing reference data. In fact, it is often the comparison of the biomass map predictions with the user-owned reference data that builds confidence in the biomass map and determines whether and how satellite-based biomass data can be integrated in specific applications. Since such comparisons are often performed, this Chapter discusses the related methodological challenges and proposes good practices to do so.

Existing reference data refer to quality forest data collected from various sources, produced for different purposes and using various methods. The main data sources regarding forest biomass include field plots, local maps and regional statistics produced by (regular) National Forest Inventories (NFIs), research forest plot networks and operational monitoring stations established for forestry, ecology or environmental purposes, as well as remote measurements of forest canopy and structure from satellite, airborne and/or UAV sensors. These data sources offer different types of validation opportunities – either through a comparison of regional averages from biomass maps with averages from statistics or gleaned from plot samples, or at the pixel-level when high-quality ground plots and/or airborne lidar maps are available.

The existing datasets can be used as reference for the validation of biomass maps, assuming they are properly screened, processed and mutually harmonized with the maps to validate. Indeed, the validation can be performed at pixel-level when the plot data satisfy the quality requirements indicated below (see 6.2.1), otherwise the validation should be performed using aggregated data at a regional scale (see 6.2.2.d).

**It is recommended** that the compilation and use of these existing reference data is done with caution and with careful attention to their characteristics and specific uncertainties. The reliability of the validation results is affected by the uncertainty of the reference data themselves and the uncertainty due to their harmonization with the map to validate. Since the existing reference data have been produced for different purposes, they need to be carefully screened and harmonized to take into account their reliability and representativeness of the study area.

The reference data are also estimates of biomass and therefore affected by errors, but they should be of higher quality than the map to validate, as recommended by the IPCC Guidelines (Herold et al., 2019; IPCC, 2019). In particular, imperfect conceptualization, measurement techniques and models of the reference data are especially important as they may cause systematic errors that are difficult to identify and quantify. Similarly, the lack of representativeness of data in terms of spatial and thematic coverage (e.g., some regions or biomass classes may be missing or under-sampled), may lead to bias in the validation results.

The remainder of this chapter provides recommendations on screening, harmonizing and validation procedures for three types of reference data: field plots (6.2), statistics (6.3) and local maps (6.4). The following recommendations are mainly aimed to check the quality of the reference data and harmonize them with the map of interest to perform a proper comparison, which is to minimize differences due to variable definitions, spatial scale, temporal domain, etc. The Chapter does not include approaches to assess uncertainties of the reference data. All reference data contain uncertainties and there is an increasing amount of literature and approaches becoming available to quantify and propagate those. If practicable, an uncertainty assessment of the reference should be conducted and included in the assessment of the quality and uncertainties of the biomass map and the related estimations (see Chapter 2 and Chapter 4). A case study showing the importance of reference data harmonization prior to product validation is presented in Box 6.1.

## 6.2 Recommendations when using field plot data

Forest plots provide estimates of forest biomass density at the sample location and represent the most common source of reference data for calibrating and validating biomass maps. Biomass is estimated at the tree level using tree measurements and allometric models, and the sum of tree biomass divided by the plot area provides the biomass density of the plot. Errors in the plot estimates vary depending on the field protocol and the appropriateness of the wood density and allometric models (see Chapter 2). If error sources are not independent, the plot estimates may present systematic errors that propagate to the validation of the biomass map. Further errors

may originate when the field plots are compared directly to the biomass map, due to various mismatches (e.g., spatial, temporal, definition) (see Chapter 3). Hence, it is essential to carefully screen and harmonize the field plots with the map to obtain reliable validation results. An overview of the screening and harmonization process for field plots in the form of a decision tree is provided in Fig. 6.1.

**Figure 6.1** Decision tree for using field plots in the validation of a biomass map. The numbers refer to the sections of this chapter.

### 6.2.1 Screening of the reference plots

The **recommended** minimum criteria for using reference plot data for validation purposes are:

1. Metadata are available including, at minimum, the definition of biomass (what parts of the tree are included), the method used to estimate biomass, the reference year(s) and the plot size. Optimally, the metadata also provides the tree parameters measured, the forest definition, the allometric model for biomass estimation, the plot shape, and the uncertainty of the biomass estimates are provided or can be estimated from the metadata.
2. The plot provides quality biomass estimates, meaning that the allometric model is considered appropriate to the forest type to which it is applied, and uses sufficient parameters (DBH and wood density and/or height).
3. The biomass definition matches, or it can be adjusted to, the definition employed in the map to validate (see 6.2.2.1).
4. Plot area is larger, or can be upscaled, or is representative of the forest area within the pixel. The area of multiple plots located within the same map pixel can be summed. If the plot size is smaller than the pixel (or, in pixels not fully forested, smaller than the forest area within the pixel), the plots need to be either upscaled using airborne lidar or other high-resolution data, or screened to assess if it is representative of the pixel (See 6.2.2.2). Even though NFIs usually employ design-based sampling designs and measure numerous but small plots (< 0.1 ha), larger plots (> 0.25 ha) are preferred for map validation because small plots present large plot-to-plot variation in biomass density, and errors associated with edge effects can be considerable, as the inclusion or exclusion of a single large tree can strongly influence the plot estimate. This is especially relevant in dense tropical forests where most of the biomass is found in few largest trees (Bastin et al., 2015; Slik et al., 2013), which can easily be over or under-represented by small plots, causing large sampling errors (Réjou-Méchain et al., 2014). Moreover, geolocation errors cause larger discrepancies between reference plots and maps in areas with high spatial heterogeneity in biomass (see Section 3.1).
5. Coordinates were acquired with GPS/GNSS devices with approximation at meter or sub-meter level (i.e., 4-6 decimals for coordinates in decimal degree). Plot geolocation uncertainty should be acceptable in relation to the size of the plot and of the map pixels (i.e. higher accuracy is needed with small plots and small pixels to reduce co-registration errors). Ideally, information on the number of GPS/GNSS measurements and how they were taken on the field (e.g. at the plot center or corners) should be available (see Section 3.1).

6. The year of measurement of the plot is within  $\pm 2$  years difference from the map reference year, or up to  $\pm 10$  years if the plot biomass is updated to the map using growth and mortality rates (see 6.2.2.3), and change datasets derived from multi-temporal high resolution satellite observations indicate that no relevant forest change process occurred in the meantime. Forest change (e.g., deforestation, degradation or afforestation) can be identified through visual analysis of recent very high-resolution images (e.g., Google Earth) and/or from forest change maps and disturbance datasets (e.g. M. C. Hansen et al., 2013). The plots not representative of the state of the land at the time of acquisition of the satellite data used to produce the map should be discarded.

## 6.2.2 Harmonization of reference plots with maps

Existing reference field plots that pass the screening phase need to be harmonized with the map to validate for the following aspects:

1. Biomass definition

Field plots collected from various sources may provide estimates of different biomass compartments, and need to be harmonized to the same biomass definition of the biomass map using conversion or expansion factors (see Neumann et al., 2016; Vidal et al., 2016). For example, plot data may exclude the stump, the small branches and the foliage, or the trees below a certain DBH but may include palms or dead trees, while the map of interest may refer to the total aboveground biomass of all living trees. This also applies to reference data of Growing Stock Volume (GSV), which can be converted to biomass if appropriate conversion and expansion factors are available. However, the conversion of the GSV at stand level is less accurate than using appropriate allometric models at the tree level, and therefore **it is recommended** to perform the conversion at the tree level where possible.

2. Spatial overlap

Field plots and map pixels may present substantial spatial mismatches due to co-registration errors, the effect of incident angle, different plot sizes and shapes, and alignment between field plots and map pixels (see Section 3.1). When the plots are larger than the map pixel size, the map can be aggregated and aligned to match (as closely as possible) the plot area coverage. When the plots are smaller than the pixels, the use of field plots for the validation of the biomass map needs to be carefully evaluated. If available, airborne lidar or similar high-resolution data can be used as an intermediate layer to upscale the plot estimate to the pixel area using a multi-step approach (see Section 3.2). Otherwise, in order to perform a proper comparison of plots and pixels, the representativeness of the plots should be carefully evaluated (see below).

In any case, if plots and maps are provided in different geographic reference systems, first they need to be converted to the same reference system before comparison. Field plots can usually be treated as vector data and re-projected without deformation, and therefore it is preferable to use this option whenever possible. If the map needs to be projected (e.g., projection to an equal area reference system necessary for quantifying the biomass stocks), it is important to apply the most accurate approach (e.g., oversampling the map to a finer spatial resolution) because re-

projecting a raster dataset always introduces some approximation in the resampling process. Such approximations become more relevant with large map pixels (> 100 m) and when there is a large difference with the area of the field plots.

Then, the plot representativeness of the biomass density of the corresponding pixels should be assessed considering the following elements:

- a) Alignment. When the plot is overlapping two or more pixels, the biomass density of the overlapping pixels should be computed as an area-weighted average, where each pixel contributes according to the fraction of the plot area located in the pixel.
- b) Forest cover. If the pixel is not fully forested and the biomass outside forest is negligible, the biomass density of the forest plots should be multiplied with the fraction of forest cover (%) within the pixel to obtain the reference biomass density of the forest area within the pixel, which can be compared with the respective value provided by the biomass map. In case the biomass outside forest is not negligible, it should be estimated using a local or default biomass density value for the non-forest land cover classes and combined with the biomass density within forest using an area-weighted approach to estimate the reference value for the pixel(s). This step requires a forest map with higher spatial resolution than that of the biomass map. This correction is necessary only if the map provides the biomass density of the land area (i.e., the biomass density over the entire pixel) while it is not necessary when the map already applied a forest mask and provides the biomass density only of the forest areas within the pixel (i.e., non-forest areas are set to “no data”).
- c) Representativeness. The plots should be screened to assess if they are representative of the forested areas located within the pixels. In fact, the biomass variability within a forest can be very large, and the small plots may not be representative of the mean biomass density within the forested area of the pixel. Representativeness may be assessed using a higher resolution map (Avitabile & Camia, 2018), radar images (Mermoz et al., 2015) or visual analysis of optical images (Avitabile et al., 2016) able to describe the biomass variability within the larger map pixels. The higher resolution product can be a map or satellite image representing or sensitive to a forest structural parameter related to biomass such as tree height or tree cover. The plots shall be discarded when they are located within pixels with substantial variability (e.g., large standard deviation) of the proxy variable (e.g., tree cover or height), and when the higher resolution map or images show that the plot is located in an area of the pixel that is substantially different from the mean conditions of the pixel. If multiple plots are located within the same pixel, the plots can be averaged. If these plots have different size, their biomass density should be combined with an area-weighted average, while a simple average can be used if the plots have the same size. If a plot overlaps multiple pixels, the plot representativeness should be assessed for all pixels where a substantial part of the plot is located (e.g., the pixels with > 20% of the plot area). Note that in a high biomass, closed canopy forest, multispectral data may appear relatively homogeneous despite considerable variability in

biomass on the ground, and validation becomes particularly challenging. In such cases with map biomass density higher than ~130 Mg/ha (P. Zhao et al., 2016) **it is recommended** to use plots that follow the recommendations from Chapter 2 and 3, if possible.

- d) Spatial aggregation. In case the plots are not representative of the biomass density of the pixels or the representativeness cannot be properly evaluated due to the lack of higher resolution data, the plots should be either discarded, or aggregated and compared with the respective pixels at a coarser spatial resolution (e.g., 0.1° grid cells). The aggregation consists on computing the mean biomass density of all the plots located within the coarser grid cell and compare it with the mean biomass density of the corresponding pixels (i.e., not all the pixels within the 0.1° grid cell but only those where the plots are located). This approach allows reducing the uncertainty due to the spatial mismatch by comparing local average values to assess systematic differences in mapped predictions of biomass at a coarser resolution, but does not produce an assessment of native pixel-level uncertainties.

### 3. Temporal domain

Field plots collected from different sources may refer to different periods and may differ by several years with the reference period of the map. Therefore, the plot data need to be adjusted to the year of the map considering the natural growth and mortality of the trees, given that plots affected by substantial forest disturbance were already identified and removed in the screening phase (see 6.2.1.6). Natural tree growth and mortality is relevant when a considerable period (> 2 years) occurred between the acquisition of the ground observations and the satellite data used to produce the map. However, the modification of the biomass values provided by the reference plots is likely to introduce substantial uncertainty and should be avoided, discarding the reference data from the validation exercise, unless it can be performed with local and/or reliable information. This temporal difference can be quantified and corrected using net growth rates (including mortality), or modelling approaches such as forest growth models. In absence of local/national and species-specific growth rates, the IPCC Tier 1 aboveground net biomass growth rates in natural forests (IPCC, 2019) may be used, if considered appropriate to the local forest conditions.

## 6.2.3 Validation approaches with reference plots

### 1. Inference methods

The choice of the validation approach should consider the statistical design of the reference data. Reference plots acquired by a NFI for biomass estimation are commonly based on a probability sampling design, and can be used for the validation of a biomass map for the same forest area represented by the NFI applying conventional design-based statistical inference methods if the plots have negligible uncertainty or hybrid inference methods if the plots have non-negligible uncertainty (see Chapter 4). However, the validation of biomass maps for areas not covered by

(or not matching the area of) a single NFI requires the collation of different plot datasets, likely acquired using a variety of plot sizes and sampling designs. Such complex amalgamated samples should be treated as an opportunistic (or, ad-hoc) sample that require model-based inference frameworks. The validation approaches also need to take into account that NFIs are concerned only with the forest area of a certain country or region while a biomass map may also include areas outside forests.

## 2. Validation metrics

The validation metrics used to assess the map accuracy can vary based on the user requirements (e.g. Chapter 5). In general, the comparison of the map and reference data should provide the uncertainty related to systematic deviation (or bias) and precision for the complete dataset (i.e., using all validation data, over the complete range of biomass values) and by biomass classes, and ideally it should provide a full error distribution as a function of biomass. Common metrics as bias and Root Mean Square Error (RMSE) assume unbiased reference data and, since this is difficult to prove, it may be more appropriate to refer to systematic deviation instead of bias and Root Mean Square Deviation (RMSD) instead of RMSE. Systematic deviation refers to the systematic difference between the map predictions and the plot reference values, and equal bias when the plot values (which themselves are estimates) are unbiased. Systematic deviation is often the most significant error and, since it varies across the biomass ranges, it should be reported by biomass class. The RMSE / RMSD is a very commonly used metric, but when reported alone is not a strong indicator of uncertainty as it mixes systematic deviation and precision.

## 3. Propagation of uncertainties

Reference plot data are themselves not error-free and therefore comparisons between maps and plot data should be accompanied by an uncertainty analysis taking into account the various sources of error (see recommendations from Chapter 4). The first step in such analysis is definition of the error model. The various error sources can be considered with an additive model expressing the unknown residual between a map prediction and plot value at location  $x$  as the sum of five components: the map biomass error at location  $x$ , the plot measurement error (which includes a plot size effect, see Réjou-Méchain et al., 2017), the positional error component, the within-pixel sampling error component (when the plot size is smaller than the map pixel) and an error introduced at a data harmonization step. Map pixels partly covered with forest undergo a harmonization procedure to scale to forest areas. Note that these five components are random variables whose values are unknown but can be described by probability distributions (Heuvelink & Snepvangers, 2005). Assuming the error terms in the equation above are mutually uncorrelated, the total error variance equals the sum of the variances of the individual error terms.

## 6.3 Recommendations when using regional statistics

Reference data for the validation of biomass maps can be obtained from NFI or forest management plans in the form of statistics (e.g., the mean biomass density of an area). It is important to consider that the statistics provided by the inventories are derived from field plots

using an estimator appropriate to the probability sampling design of the plots, while the values from the map are obtained by averaging (in the case of the mean) all pixels within the region of interest. As in the case of field plots (Section 6.2), reference statistics also need to be screened to select reliable and accurate data and to be harmonized with the map to validate. Moreover, when combining different reference statistics, such as NFI from different countries or NFI and forest management plans, the statistics need to be harmonized among each other if they present differences regarding the forest definition, the biomass definition and the temporal domain. An overview of the screening and harmonization process of reference statistics in the form of a decision tree is provided in Fig. 6.2.

**Figure 6.2** Decision tree for using regional statistics in the validation of a biomass map. The numbers refer to the sections of this chapter.

### 6.3.1 Screening of the reference statistics

The minimum criteria for using reference statistics for validation purposes mostly correspond to those indicated for reference plots:

1. Metadata are available as described in Section 6.2.1.1, and include also the number of plots used to develop the statistics.
2. The statistics provide quality biomass estimates, as described in Section 6.2.1.2.
3. Biomass definition matches, or it can be adjusted to, the definition employed in the map to validate (see 6.3.2.1)
4. The reference year of the statistics is within  $\pm 2$  years difference from the map reference year, or up to  $\pm 10$  years if the biomass statistics are updated to the map for natural growth, mortality and forest change, as described in Sections 6.2.1.6 and 6.3.2.3.

### 6.3.2 Harmonization of reference statistics with maps

Existing reference statistics that pass the screening phase may need to be harmonized with the map for the following aspects:

1. Biomass definition

Reference statistics, especially when coming from different sources, may refer to different biomass compartments, and need to be harmonized to the same biomass definition used in the biomass map as described for reference plots (see 6.2.2.1).

2. Spatial domain

Reference statistics typically refer to only forested areas, and thus a forest mask needs to be applied to the biomass map to compare the biomass stock and density of the map over the same (or comparable) forest area indicated by the statistics. The forest mask shall employ the same forest definition used in the reference statistics, and present a comparable forest area in the spatial units of the statistics (usually, sub-national administrative units).

3. Temporal domain

Reference statistics, as described for reference plots (see 6.2.2.3) may need to be adjusted to the year of the map considering the natural growth and mortality of trees, using net growth rates (including mortality), or modelling approaches such as forest growth models or carbon budget models. In the absence of local/national and species-specific growth rates, the IPCC Tier 1 aboveground net biomass growth rates in natural forests (IPCC, 2019) may be used, if considered appropriate to the local forest conditions. If forest change processes (i.e., deforestation, degradation or afforestation) are identified from existing forestry statistics, from forest change maps and datasets, or through visual analysis of very high-resolution images (e.g., Google Earth), the reference statistics should be discarded, unless they can be corrected with local and/or reliable information. This correction requires the knowledge of the type of change that occurred (complete versus partial removal, or increment rate for new forests), the forest type where it

occurred and the amount of biomass affected by the change. If the forest loss occurred after the reference year of the statistics but before the reference year of the map, the statistics of the corresponding forest type may be adjusted using forest growth models or simply in proportion to the forest area change.

### **6.3.3 Validation approaches with reference statistics**

The recommendations related to the inference methods and validation metrics provided for field plots are also applicable to the reference statistics (see 6.2.3). In addition, the biomass map needs to be aggregated for each spatial unit of the NFI or management plan, such as a sub-national administrative unit or a forest stand, and compared with the respective reference value. However, these spatial units may have very different area coverage, which should be reflected in the validation approach by weighting the reference value according to the forest area of the spatial unit.

For example, the RMSE/RMSD of the biomass map can be computed as a weighted mean of the differences between the statistics and the map for each spatial unit, where the weights correspond to the forest area percentage of each spatial unit to total forest area. In this way, the reference statistics representative of larger areas will be given a corresponding weight in the computation of the map accuracy.

## **6.4 Recommendations when using high-quality local maps**

Currently, there are large areas of the globe where forest plots and statistics are either missing or scarce due to the inaccessibility of the forest or lack of forest management and inventory systems (e.g., in some areas of the tropics). In other cases, reference data may exist but they are outdated (e.g., in boreal forests of Eurasia), or not accessible to researchers for various reasons. In such cases, a possible source of reference data may be found in local biomass maps that are considered of greater quality than the map to validate. Such datasets consist of biomass maps that usually have national or subnational coverage, are produced using local field plots and/or airborne lidar data, and can provide reference biomass values at a spatial scale intermediate between field plots and regional statistics.

These local maps can be used to obtain reference data using a sampling approach (e.g., systematic, random, stratified, etc.) to extract a certain number of reference map pixels (see 6.4.3). However, if the reference map has a substantial uncertainty at the pixel-level but it is assumed to provide estimates without systematic at regional scale, it can be used to compute reference statistics (e.g., mean biomass density) over appropriate areas, such as administrative units stratified by ecoregions or forest types, and use these reference values for the map validation as indicated in Section 6.3.

An overview of the screening and harmonization process of reference maps in the form of a decision tree is provided in Fig. 6.3.

Figure 6.3 Decision tree for using local high-resolution biomass maps in the validation of a large-scale biomass map. The numbers refer to the sections of this chapter.

### 6.4.1 Screening of the reference maps

Local, high-quality biomass reference maps should present the following characteristics:

1. Metadata are available, including at minimum the definition of biomass employed, and the reference year(s). Optimally, the metadata also provide the forest definition, the allometric model for biomass estimation, the number of plots, the plot size, the remote sensing data and the mapping approach used to develop the map, the uncertainty of the biomass estimates at pixel level and the accuracy at map level.
2. The reference maps provide quality biomass estimates, meaning that the map is calibrated with a sufficient number (e.g., > 30) of quality ground plots, possibly combined with airborne lidar data and/or high resolution satellite data, and the input data and the mapping approach are appropriate to the forest type(s) to which are applied (e.g., the maximum biomass in the area is below the saturation level of the remote sensing data).
3. The biomass definition of the reference map matches, or it can be adjusted to, the biomass definition employed in the map to validate (see 6.4.2.1).
4. The spatial resolution of the reference map is higher than (or equal to) that of the map to validate.
5. The reference period of the reference maps is within  $\pm 2$  years difference from the map to validate, or up to  $\pm 10$  years if the reference map is updated to the map to validate using growth and mortality rates (see 6.4.2.3).

### 6.4.2 Harmonization of the reference maps

Existing reference maps that pass the screening phase need to be harmonized with the map to validate for the following aspects:

#### 1. Biomass definition

The reference maps may refer to different biomass compartments, and need to be harmonized to the same biomass definition used in the map to validate using conversion or expansion factors (see Neumann et al., 2016; Vidal et al., 2016). For example, the map to validate may refer to the total aboveground biomass of live trees while the reference maps may exclude the stump, the small branches and foliage, and the trees below a certain dbh.

#### 2. Spatial overlap

The reference maps are expected to have a higher spatial resolution than the map to validate and need to be aggregated and aligned to match (as close as possible) the map to validate. If the maps have different reference systems, one of them needs to be projected before the aggregation. Since re-projecting a raster dataset always introduces some approximations in the

resampling process and such approximations become more relevant with large map pixels, it is advisable to re-project the map with higher spatial resolution.

### 3. Temporal domain

The reference maps may differ of several years with the reference period of the map to validate and need to be adjusted to the year of the map to validate considering the natural growth and mortality of trees, and the occurrence of forest change processes. However, the modification of the reference maps is likely to introduce substantial uncertainty and should be avoided, discarding the reference data from the validation exercise, unless it can be performed with local and reliable information. In such cases, it should follow the same approach indicated for the reference statistics (see 6.3.2.3)

## 6.4.3 Validation approaches with the reference maps

### 1. Selection of the reference pixels

Only the cells with largest confidence (i.e., smallest uncertainty) should be selected from the reference maps and used as reference data. If the reference maps are based on empirical models, the map cells with greatest confidence are assumed to be those in correspondence of the training data (field plots and/or lidar data). Uncertainty maps can also be used to identify the map cells with smallest uncertainty. For maps based only on radar or optical data, whose signals saturate above a certain biomass density value, only pixels below such a threshold should be considered.

### 2. Amount of reference data for validation

If multiple reference datasets are available (i.e., including both field plots and high-resolution maps), in order to compile a reference database that is representative of the area of interest and well-balanced among the various reference datasets, the amount of reference data extracted from the reference biomass maps should be proportional to their area and not greater than the number of samples provided by the field datasets representing a similar area (e.g. Avitabile et al., 2016).

### 3. Statistical inference for validation

When using a biomass map as a source of reference data, it is important to first assess the accuracy of this map. McRoberts, Næsset, Liknes et al. (2019) provide guidance on using a local biomass map as source of reference data to assess the accuracy of a large-scale map. They considered that, even if the local map is of greater quality, it provides reference data that are likely to have non-negligible errors and that could be affected by systematic errors. Since the design-based estimators assume that reference data have at most negligible uncertainty (Snedecor & Cochran, 1967), they recommend the use of hybrid inferential techniques for assessing the uncertainty of the reference data extracted from a map. The hybrid inference consists of methods that combine model-based inference to estimate uncertainty due to the errors in the reference data and design-based inference to estimate uncertainty due to sampling from the finer resolution map (Ståhl et al., 2016). McRoberts, Næsset, Liknes et al. (2019) also

suggest expressing the uncertainties of the map estimates as Mean Square Error (MSE), or Mean Square Difference (MSD) that differently from MSE does not assume unbiased reference data, rather than variance because the map-based estimators of the means are not necessarily unbiased.

**Box 6.1**

This case study shows the impact of the harmonization of the reference data on the validation results. We assessed the global biomass map for the year 2010 produced by the GlobBiomass project (Santoro et al., 2018) for the area of Europe using national statistics. We performed the validation four times, using different levels of harmonization of the reference data. First, we computed the total biomass stock per country from the map and compared the results with the most recent statistics provided by the National Forest Inventory (NFI) for 21 countries, using the relative RMSE (defined as RMSE divided by the mean value of the reference data) as measure of accuracy. The NFI reference data use country-specific definitions and parameters, and are not harmonized among themselves and with the map to validate in terms of forest definition, biomass definition, and reference period. Hence, in a second step we harmonized the NFI reference statistics to the same biomass definition employed by the biomass map using country-specific biomass correction factors (see Avitabile & Camia, 2018). Then, in a third step we further harmonized the statistics to the reference year of the biomass map (2010) using the Carbon Budget Model (CBM-CFS3) developed by the Canadian Forest Service and adapted to the specific European conditions (Pilli et al., 2018). Lastly, as the fourth step, we repeated the previous validations accounting also for the differences among forest definitions. This was done by applying a forest mask to the biomass map, in order to quantify the biomass stock of forest areas only. Among the numerous forest maps available for Europe, we selected the Copernicus Forest Map for the year 2012 because it was the map best matching the NFI statistics on forest area at European level. Nonetheless, in some countries, the difference in forest area between the NFI statistics and the map was still relevant, and thus we selected only the countries (16) where such differences were smaller than 15%, to reduce the impact of different forest areas in the validation results.

The validation results show that the agreement between the reference statistics and the biomass map increased at each step of the harmonization process, with the relative RMSE decreasing steadily from 24% to 15% when the reference statistics were harmonized for biomass definition, temporal resolution and forest definition (Fig. 6.4). In other words, a substantial part of the difference initially found between the reference statistics and the biomass map was only due to the lack of harmonization and not to “errors” in the biomass map. This analysis shows the importance of the harmonization of the reference data for a fair and accurate assessment of the biomass maps.

**Figure 6.4 Validation results of the GlobBiomass map** using the original national statistics (“National statistics”, left), the statistics harmonized for biomass definition (“Biomass harmonized”, centre), temporal resolution (“Biomass harmonized 2010”, right) and forest area (orange bars)

## 6.5 Summary and current knowledge gaps

This chapter provides guidance for the use of existing biomass reference data to validate biomass maps. Validation data should be independent of the map production process and should ideally be coming from a design-based reference sample. However, the scarcity of biomass reference data often makes it necessary to use existing and available biomass data produced for various purposes, which may be based on a statistical design tailored to a different objective or study area. The collation of existing reference data is likely to produce an “opportunistic” dataset that may not fully represent the biomass variability within an area of interest. Hence, it is important to test which ecoregions, forest types and biomass ranges are most under-sampled and should be subject to additional data acquisition exercises. The use of lidar (from airplanes, drones and terrestrial) is an important evolving source of reference data for both calibration and validation purposes.

This chapter includes only marginally the consideration of the uncertainty of the reference data itself, but this aspect is treated in more detail in Chapter 4. In fact, assessing the quality of the reference data is very important to obtain reliable validation results, and requires further attention and more examples and approaches to make it an essential part of any upcoming map validation exercise.

# Chapter 7: Knowledge and Data Gaps

This chapter seeks to summarise the gaps and pressing areas for new data and research identified in previous chapters. The authors who have compiled the overviews in each case were asked to consider where there might be a need for new measurements, models and methods in order to improve our ability to both derive and assess AGB from EO data across scales and biomes. The gaps identified inevitably reflect the various different requirements when AGB is used for different purposes and applications.

## 7.1 Generation of reference datasets

A consistent framework to define, quantify and propagate errors from field data underpinning all reference data sets through to generation of AGB estimates from these data, or their use in assessing the quality of EO-derived estimates.

To achieve this requires a number of issues to be addressed. Firstly, accurate plot location (>> geolocation of EO estimates), agreement on how edge effects are to be dealt with, and co-location of spatial / EO-derived estimates. As outlined by Clark and Kellner (2012), a global database of biomass harvest plots will require a significant research commitment to improving our ability to quantify measurement errors in ground-based estimates of biomass, and how these may be minimised.

Key gaps here include:

### Plot location

- Common consensus and guidance on how to accurately locate ground-based plots, their orientation, boundaries and 'edge effects' i.e. missing in/out trees. This is in addition to considering whether there is a 'desirable' size and/or shape of plots and what those should be. The issue of edge effects will be particularly important for EO estimates derived from observations made at oblique angles (e.g. radar). The impact of edge effects is likely to decline with increasing plot area.
- How to deal with uncertainty in co-location of EO footprints is of particular importance. The location accuracy of EO footprints varies from product to product and so this needs to be considered in the definition of ground plot location.
- Consistency in measurement protocols for seemingly commonly-measured properties (H and wood density for example).
- Clear consideration of the trade-off between individual and stand-scale accuracy: at the stand-scale, sampling intensity has a much greater impact on precision of basal area (and hence, stand biomass estimates) than other factors such as the height of the stem, size and form of the individual and tool used.

## Allometric models

- Agreement over the form and type of allometric regression models to be used, their definition, and clear statement of assumptions that are made in employing a particular model and how the estimates of uncertainty in the model parameters and predictions have been quantified. Tools exist to do this but they should be adopted as a matter of course.
- Consideration of the issue of local v general models: there is evidence to suggest that locally-calibrated models may be better than general models (aggregated regionally or across species or biome type etc) in some cases, but not always or by much.
- Wood density

## TLS and UAVs

TLS and more recently UAV lidar are acknowledged as being potentially transformative technologies to derive tree- and plot-scale estimates of tree volume and hence AGB. This opens the possibility for direct estimates of wood volume and AGB at the same scale as EO estimates; improved allometric models with many more tree samples; improved characterisation of the uncertainty in allometry-derived estimates. Calders et al. (Section 2.3) identify the following potential gaps and requirements for TLS and UAV data collection for AGB estimation:

- A need to systematically incorporate TLS as local calibration data to refit current allometric biomass equations i.e. as more trees are sampled with TLS, allometric models should be re-derived with improved uncertainty estimates NB this doesn't necessarily imply **reduced** uncertainty, but better-characterised.
- Systematic, ideally automated, location of stems in TLS and census data. Ideally this would be automated via markers, quick response (QR) codes etc. rather than manual (Disney, 2019) but at the very least every effort needs to be made to match stems in both samples to enable species and wood density attribution in the lidar data.
- Improved estimates of wood density to reduce uncertainty related to volume-to-mass conversions. Improved (semi-)automated tree species recognition would also help in this attribution.
- Tool development: full automation of structural retrieval i.e. extraction of single trees from larger point clouds, and then volume fitting (or even volume fitting to larger plot-scale point clouds) e.g. can we develop plot-level volume-fitting algorithms as a "plug & play" approach?
- Tool development: interface development to make volume-fitting algorithms more user-friendly and accessible, automated over large numbers of trees.
- Tool development: a quality control (QC) framework that includes quantification of uncertainty of volume estimates at tree level, as well as uncertainty of plot-level AGB estimates.
- Tool development: routine integration of UAV-LS methods can bridge the (data) gap between ALS and TLS. UAV-LS should not be seen as a replacement for ALS or TLS (or both) but as a new measurement somewhere between the two. Extracting information on AGB will use elements of processing methods from both ALS and TLS, but will likely

also require new dedicated methods to take into account the particular nature of the measurements.

## 7.2 Linking reference plots to satellite data

Réjou-Méchain et al. (Chapter 3) discuss the requirements for linking reference plots to EO estimates, particularly the impact and possible mitigation of mismatches in space and time. They make the point that a key requirement is clear definition of context for the use of EO data i.e. the purpose for which they will be used needs to be very clearly defined, as this will determine the minimum plot size, as well as the acceptable time gap between ground and EO data collection.

Réjou-Méchain et al. use the example of ESA BIOMASS with 50 m footprint and 30° view/illumination incidence angle (often used in radar to minimise impacts from soil roughness) can cause a large mismatch with smaller validation plots. There is therefore a need for making co-registration accurate and reducing edge effects by increasing plot size. Larger plots will also tend to reduce temporal differences. Thus, the size of the plots and the spatial scale at which the RS product is calibrated or validated should be large enough to minimize these errors.

## 7.3 Linking field plots to spaceborne data using airborne lidar

Large and small footprint ALS have long been established as tools for near direct estimation of canopy height and cover, and subsequently through empirical modeling AGBD. Both capture landscape scale variation in structure, providing a bridge between EO and local scale observations (UAV-LS, TLS, field). Large footprint lidar systems (e.g. NASA LVIS) enable rapid and large area wall-to-wall or transect acquisitions (e.g. entire countries in some cases) but are of limited availability, however small footprint ALS systems are now capable of this scale of acquisition as well.

A key issue for global validation of EO products are practical and logistical constraints on ALS data acquisition. Government restrictions on ALS data availability (e.g. China, India) and flight authorization (e.g. Brazil) can make access to existing data or acquisition of new data difficult. Depending on transit distance and areal coverage required, ALS data acquisitions can be expensive, with estimates on the order of \$250 –\$600 per km<sup>2</sup> (in US dollars) for small footprint ALS (Réjou-Méchain et al., 2019). Non-commercial instruments such as NASA facility instruments can acquire much larger areas than current commercial small footprint ALS systems for the same cost, however they are not as readily accessible and may incur large transit costs.

**The following are recommended** when producing a reference ALS AGBD map for EO biomass map validation. These are in addition to recommendations on linking field plot data with ALS data that are aimed at minimizing the impact of geolocation error and plot size (Section 3.2).

- Use recent, high-quality, well-vetted lidar instruments and survey configurations
- Acquire wall-to-wall data that are spatially and temporally coincident with field plots
- Develop local AGBD models using an area-based approach
- Adopt a statistically rigorous framework for reference map generation

We have identified the following gaps in methods development and tools to enable systematic validation with a global set of linked field plots and ALS AGBD reference maps:

- A quality control framework for AGBD map production
- Improved uncertainty estimates at the pixel level that account for multiple sources of error (see Chapter 4)
- Methods to aggregate AGBD uncertainties from ALS pixel level to the spatial resolution of EO map products
- Evaluation of ALS metric repeatability and biomass model performances when applied to ALS datasets from new instruments or acquisitions that are not coincident with field plots.
- A tool for propagation of *in situ* and ALS measurement and model errors (see Chapters 2 and 4) to the resolution of EO AGBD products that is accessible and standardized
- A tool for comparison of local maps derived from ALS to global maps derived from EO at multiple spatial resolutions and by user defined strata

## 7.4 Characterization and propagation of error

Roxburgh and McRoberts (Chapter 4) provide systematic definitions and assessment of the nature of error and uncertainty in estimates of AGB. They make the point that adherence to the IPCC good practice guidelines should be a key consideration of any measurement of AGB, namely: (i) “neither over- nor underestimates so far as can be judged” and (ii) “uncertainties are reduced as far as practicable” (GFOI, 2016, p. 15).

- Therefore when developing new or using existing biomass maps, estimates based on those maps are required to comply with these guidelines. In general terms this means ensuring that estimates are either obtained or evaluated using unbiased estimators (satisfying criteria (i)), and that all of the key error sources are recognised and accounted for, and that the methods applied are rigorous, appropriate, and quantifiable (satisfying criteria (ii)).

Roxburgh and McRoberts make the distinction between design-based and model-based inference and point out that “on its own traditional design-based inference is of little utility for creating maps of biomass”.

A total of thirteen possible sources of error are identified, spanning the breadth of calculation steps from initial construction of allometric models through to the calculation of final map

biomass and its uncertainty. A generalised MC approach is given to show how these errors can be propagated through to AGB estimation. A key requirement therefore is the specification of these errors in any attempt to estimate AGB, and then how these are propagated to the final maps.

## **7.5 Considerations for utility of the CEOS biomass protocol: user communities**

### **7.5.1 Utility for LSM, DVM modelling communities**

Williams, MacBean and De Kauwe (Chapter 6) consider the requirements of AGB estimates for the various C-cycle modelling (LSM, DVM) communities. They note the range of modelling scales (time and space) to which AGB is relevant e.g. to address issues of within-plant allocation of carbon and turnover rates of these issues, as well as the individual- to community-scale rate of productivity i.e. the difference between photosynthesis and carbon losses (respiration and turnover of plant tissues). They make several recommendations for the validation requirements of biomass products for these modelling efforts:

- That biomass products are integrated within community land model benchmarking schemes such as the International Land Model Benchmarking (ILAMB) project.
- To maximise value for DVM validation, clarity on the relationship between height and biomass estimates should be provided i.e. specification of whether these measurements are correlated or independent.
- Uncertainty metrics should be provided with/linked to all biomass and height data products. Metadata should explain the nature of the uncertainty estimate and its derivation.

### **7.5.2 Policy-relevance**

Herold et al. (2019) discuss the policy requirements and evolving needs for biomass map data being properly and independently validated in a way that it is technically robust (as described in this protocol) and useful for different policy applications and users. They make the point that a one-size fits all approach will not work so a key requirement is that

- Development and assessment of biomass products should be by both producers and users in concert.
- National level estimates may be most relevant for country GHG inventories.
- The final biomass estimate needed by the users that can be the total or average biomass per country or forest type or a local/pixel-specific value

- Requirements of whether a biomass estimate is needed for one time (i.e. one year) or for multiple years and whether it includes the estimation of biomass changes
- As above for uncertainty: compliance with IPCC good practice guidelines: (1) “neither over- nor underestimates so far as can be judged,” and (2) “uncertainties are reduced as far as is practicable” (IPCC, 2006).

#### **For IPCC, GCOS, and for AGB ECV**

- Optimal: regular global forest biomass monitoring at 50-100 m resolution at annual intervals.
- Focus on long-term (i.e. decadal) and temporal consistency as input to global and regional climate and vegetation models
- Uncertainty and stability of ECV products are to be assessed and reported for relative and absolute systematic deviation and confidence interval or RMSE, overall and by biomass class/range estimated using reference data of better quality.
- Coordinated international activities for uncertainty characterization and reference data collection are required.

Herold et al. note that the reporting will be required at national level for some schemes and policy frameworks, but regionally for others. They also note that the requirements for uncertainty, validation and reporting will likely differ substantially between the scientific and policy requirements. For example, for in the context of REDD+ efforts:

- Uncertainty requirements vary by performance scheme.
- Consistency, accuracy and transparency should be sufficient to be convincing for technical assessments (i.e. by the UNFCCC)
- Discounts in payments due to high uncertainty or conservative adjustments possible.

### **7.5.3 Utility of protocol by non-forest communities**

#### **Savanna ecosystems**

Chapter 5 section 3 notes the importance in terms of AGB of regions not considered ‘forest’: *non-forests contribute less than 20% of global biomass, they represent half of terrestrial productivity and cover ca. 70% of the Earth’s land surface* (Pan et al., 2013). The point is that regions classified as savanna are very often structurally dominated by trees, with, on average, at least 50% tree cover coexisting with C4 and C3 tropical grasses (Lloyd et al., 2008). As a result they note a need for:

- Bespoke allometric relationships for non-forest trees should be generated via a combination of TLS assessment and destructive harvesting to enable AGB assessment of these trees.
- Consistency checks between satellite-derived aboveground biomass estimates and data on soil properties and belowground carbon storage.

- Definitions of “forest” and “non-forest” boundaries that allow for biomass dynamics to be tracked across these boundaries in a consistent and as unbiased way as possible.

### **Woodland ecosystems**

- Woodland biomass products would provide area and biomass estimates that would then be used in conjunction with models and other data to estimate total C stock changes in biomass, dead organic matter (woodland floor, coarse woody debris, etc), and soil C.
- Uncertainty would be provided as variances or covariances in total biomass C for the spatiotemporal product (covariances in time and space).

## **7.6 User-led validation with pre-existing reference data**

Avitabile et al. discuss the requirements and considerations for facilitating integration of the large amount of pre-existing reference data with new AGB estimates. Reference data for the validation of large-scale biomass maps include field plots, local high-quality maps and regional statistics. These pre-existing data are not necessarily produced or derived for the purpose of calibrating and validating biomass maps and so may not be compliant with the recommendations made above. Errors in the reference data and mismatches (e.g., spatial, temporal, definition) between the reference data and the biomass map can introduce substantial uncertainty in the validation results. However, with appropriate screening and harmonization procedures (described in the chapter) they can provide useful reference data for the EO-derived AGB estimates, as well as help to build trust and support the uptake of maps for certain users and applications. The importance of this latter aspect should not be overlooked. Avitabile et al. note in particular the following requirements:

- Screen the existing reference data according to requirements and quality/criteria for inclusion to create “opportunistic” reference datasets appropriate for the validation objectives.
- Harmonize the reference data with EO-derived maps by matching, as much as possible, the biomass definition, the spatial scale and the temporal domain of the two datasets.
- Stratify the existing reference data by ecoregions, forest types and biomass ranges to identify the strata that are most under-sampled and hence in need of additional reference data.

# Chapter 8: Implementation Considerations

This protocol has included specific recommendations for both biomass product developers and users. For the former, recommendations include how to report uncertainties when producing a map, including uncertainties from field measurements, allometric models, geolocation, and propagation to remote sensed products (both airborne as reference maps and spaceborne as global biomass products). For users aiming to interpret the uncertainties reported in products, the protocol should inform the process by which these uncertainties were (hopefully) estimated. For users wishing to conduct their own independent validation, the protocol makes recommendations for how to collect new reference data and use it to estimate uncertainties in products. There is also a chapter focused on recommendations for using existing datasets for product evaluation, which cautions against common pitfalls in this process.

For all of the above protocol uses, the fundamental limitation of both product generation and validation is the availability of high quality, globally distributed reference datasets. While many such datasets already exist, there are considerable spatial data gaps that limit the ability to estimate uncertainties in new and forthcoming biomass products over certain geographic domains. Even in well sampled areas, reference datasets require updating to be contemporaneous with satellite data used in biomass map production.

Further, it is apparent that product validation activities (both by developers and users) require consistency and transparency if reported uncertainties are to be trusted. To mobilize the use of biomass products for many applications (e.g. as inputs to carbon cycle models or use in national contributions to policy commitments) we require transparent, open source tools.

To implement the recommendations of this protocol, we require new and updated reference data (including field plots, TLS and airborne lidar datasets), and the development and refinement of tools to use these new measurements for product validation.

## 8.1 Collection of new reference data

**It is recommended** to collect new reference data at sites following the recommendations in Chapters 2, 3 and 4. Sites that follow these recommendations are termed 'Biomass Reference Measurement (BRM) sites', which are existing field stations selected based on the following requirements in terms of measurement, and where, if necessary, requirements can be met: (1) Availability of at least 10 already established 1 ha permanent sampling plots, according to the best forestry standards. Within the plot, each stem is mapped, its diameter measured, and its species is identified. The plots must have been inventoried on a regular basis in the past and be accurately geolocated; (2) Potential for airborne lidar scanning (ALS) coverage over at least 1000 ha, flown over the permanent plots; capacity to conduct new airborne lidar scanning coverage on a regular basis; (3) Potential for terrestrial lidar scanning (TLS) of a subset of the sampling

plots; (4) Availability of a weather station and automated soil moisture monitoring (ideally encompassing the landscape-scale variation of soil moisture).

- (1) Permanent forest sampling plots provide the most accurate estimates of above ground biomass, which is inferred from highly precise field measurement through allometric models. A minimal forest sampling coverage is necessary to avoid bias (e.g., selecting only mature forests as representative of a diverse landscape). Many potential BRM sites have on the order of 10 1 ha plots (either in the form of several independent 1 ha plots, or one large plot), because this sampling intensity is manageable. Larger sampling intensities do exist but they are rare. In a forest, only trees greater than 10 cm in stem diameter are commonly measured, representing between 300 and 1000 stems per hectare. Accurate tree positioning, stem diameter measurement, and tree identification are all time-consuming and require skilled personnel on-site. In regrowing forests, a large fraction of biomass is held in stems smaller than 10 cm diameter, and the reference minimal diameter is often reduced to 5 cm.
- (2) Airborne lidar scanning (ALS) has been intensively used for upscaling plot-based tropical forest biomass measurements. Calibration of the ALS data locally with permanent sampling plots results in accurate and precise above ground biomass maps over areas of typically 1000 ha (10 km<sup>2</sup>). This area is also typically within walking distance of the field station of the BRM site, and the biomass map can be thoroughly ground-truthed. Quality requirements on ALS data include high-quality global positioning of the acquisition, and a sufficiently high density of returns (at least 4 returns per m<sup>2</sup>, but preferably at least 10 returns per m<sup>2</sup>).
- (3) Terrestrial laser scanning (TLS) surveys are an essential complement to sample plot data by providing: (i) an unbiased measure of wood volume, (ii) a reliable measure of total tree height; (iii) an accurate correction of stem geolocation (relative, at stand scale). This considerably increases the quality of the key plot data on which all of the other estimates rely.
- (4) Ancillary data from weather stations or soil moisture probes are often needed in EO validation plans, and are easily obtained at sites where human revisit is frequent. Continuous measurement of these environmental observables is needed during the flying period of the missions. Data gaps should be minimized and gap-filling methods be in place to mitigate instrumentation problems.

## 8.2 Potential BRM Sites

To minimize the cost, the selected sites should preferably belong to existing networks of ground sites (Chave et al., 2019), because these sites ensure local leadership, established partnership, data quality, local knowledge on environment and botany, and historical information. Capitalising on existing initiatives where previous expertise, capacity and infrastructure have been built would also minimize cost. This principle will also benefit the data quality and, as many of these plots have a longstanding history, the context.

Figures 8.1-8.3 depict sites that have been chosen carefully from global ecological networks and initiatives representing different forest types and that have the potential to be extended to BRM sites. Appendix DD provides the site details.

We propose to select 100 of these candidate BRM sites, based on their representativeness of environmental conditions, forest types and continents. Representativeness of a BRM site is evaluated by the site contribution to major environmental conditions and forest types. Based on the sites in Figure 1, it is thus possible to select the 100 sites that maximize representativeness, but also comply with the measurement and logistical criteria.

**Figure 8.1. Location of the potential Biomass Reference Measurement sites for inclusion in the proposed CEOS Forest Biomass Reference System in the Americas (left: North and Central America; right: South America, as of August 2020. The background is the land cover CCI map for year 2015 (cf. <https://www.esa-landcover-cci.org>).**

Figure 8.2. Location of the potential Biomass Reference Measurement sites for inclusion in the proposed CEOS Forest Biomass Reference System in Africa (left), tropical Asia and Oceania (right), as of August 2020.

Figure 8.3. Location of the potential Biomass Reference Measurement sites for inclusion in the proposed CEOS Forest Biomass Reference System in Europe (left) and temperate Asia (right), as of August 2020.

How many BRM sites are needed? CEOS LPV has four stages of maturity for land products (<https://lpvs.gsfc.nasa.gov>). Currently, biomass is only at stage 1, and our ultimate goal is to achieve stage 4, but our immediate goal in establishing the CEOS Biomass Reference System is to achieve stage 3. We do not know at this time how many biomass reference sites will be needed to achieve validation stage 3. We can, however, state the level of coverage that is achieved for a given effort in relation to the key target variable (global coverage of forest AGB carbon). The Earth has a total forest cover of nearly 40 million km<sup>2</sup>, and the key variables that affect forest AGB are all extremely variable, spatially. These include temperature, moisture, soil nutrition, soil depth, slope, gross and net productivity, as well as species diversity.

Furthermore, forests in near-identical climates on different continents have very different biomass, canopy structure, and tree form due to different biogeographical history and species composition. African, South American, Asian and Australian tropical forests share almost no species, have different biomass and growth rates, and different sensitivities to climate change (e.g., Hubau et al. 2020, Sullivan et al. 2020). Finally, forests are also subject to multiple human

processes which alter structure and biomass, often creating very heterogeneous and dynamic landscapes.

Hundreds of sites are therefore desirable, but in practice we have to start from the current situation with sites that already meet or come close to meeting our criteria. There are currently about 170 of these. This suggests that at least 100 high-intensity BRM sites are an achievable target to implement the core of the proposed long-term CEOS Forest Biomass Reference System.

To first order, this ground effort should be distributed to represent the uneven distribution of biomass productivity and biodiversity across the Earth’s forests (Table 8.1). This shows the overwhelming importance of adequate representation of tropical forests, which have high biomass and productivity and very high diversity of tree species, structure and composition. Accounting for the distribution of the key biological variables suggests at least 70% of the effort needs to be dedicated to tropical forests (wet forests, moist forests, dry forests and tropical montane forests). This is a minimum given the complexity of tropical forests.

On average, 100 BRM sites provide coverage of one site per 385,000 km<sup>2</sup> of forest world-wide (Table 8.1). This sample intensity will not satisfy all the needs of the EO community. It therefore should be considered a minimum which CEOS should build on with an ambition to go further.

**Table 8.1 Site Sample Intensity for each Global Forest Zone after allocating 100 BRM sites as 70:15:15 to Tropical: Temperate: Boreal.** In each Zone, one site is allocated on average for the area, biomass, productivity, and diversity indicated here.

	Area (km <sup>2</sup> )	AGB (Pg carbon)	GPP (Pg C yr <sup>-1</sup> )	NPP (Pg C yr <sup>-1</sup> )	Tree Species
<b>Tropical</b>	278,429	3.74	0.58	0.31	671.4
<b>Temperate</b>	511,333	3.11	0.66	0.54	91.6
<b>Boreal</b>	756,667	3.59	0.55	0.17	9.9
<b>Earth’s Forests</b>	385,100	3.63	0.59	0.33	485.2

The level of sampling described above nevertheless leaves very large geographical gaps, especially in the tropics. For example, within high-biomass Amazonia the distance between many proposed BRM sites is > 1,000 km. We know from previous work that biomass, canopy height, structure, species, carbon dynamics and human impacts all vary at much smaller scales than this.

To fill these gaps, the addition of suitable sites will be assessed after the first round of product validation to get to CEOS validation stage 4.

### 8.3 Low-intensity sampling

The creation of a global network of long-term BRM sites would be a critical advance for the calibration and validation of ongoing and planned biomass missions. However, as seen above, the spatial and environmental coverage of 100 sites is necessarily limited. Moreover, there is already considerable demand from the EO user community for a much higher plot sampling intensity to validate biomass products. This demand is explicitly recognised for example by the ESA-funded Forest Observation System which seeks to acquire high-quality tree-by-tree data from hundreds of tropical plots.

We therefore propose to additionally define additional low-cost but highly distributed BRM plots, henceforth distributed BRM sites. These sites comprise just single or a few long-term 1 ha plots, and no upscaling using ALS. They do not require the long-term infrastructure of BRM sites, nor do they need a high local density of permanent plots. If during CEOS stage 3 validation it is discovered that some of these distributed BRM sites are critical to validation, they could be promoted to BRM sites.

The key rationale for including distributed BRM sites is to provide much better strategic gap-filling than is otherwise possible.

The number of these is still limited by what is available. Currently, there are at least 1,100 high-quality, networked, recensused tropical forest plots (including some >1 ha). Of these, up to 500 (700 ha) will be included in the 70 core tropical BRM sites. But the remaining 600 plots are more widely distributed, alone or in small clusters, in more than 300 sites. Discounting those which are close to BRMs still provides a sufficient number of sites from which to easily select more than 200 additional distributed BRMs with an average of two plots in each.

**It is therefore recommended** to include 210 additional, distributed BRM sites. This allows the proposed CEOS Forest Biomass Reference System to optimally fill the large gaps between tropical BRMs, and achieve an overall tripling of the tropical site sampling intensity compared to that proposed in Table 8.1. Including these in the CEOS Forest Biomass Reference System through periodic re-censuses at each site contributes to the global integration of the ground-based and remotely-sensed forest observation communities, while providing an ‘easy win’ to ensure sampling captures the complex variation in biomass and biomass change in the tropics. By designating these as distributed BRM sites, the Earth Observation community also efficiently leverages a large historic investment in monitoring some of the more remote forests on Earth.

## 8.4 Validation tools

To mobilize the ingestions of these new and updated reference measurements for validation of biomass products, we require open source, transparent validation tools. One example of the type of software that enables uncertainty estimation is the BIOMASS package in R (<https://cran.r-project.org/web/packages/BIOMASS/index.html>, Rejou-Mechain et al. 2017). The extension of these tools to include the measurement and allometric modeling uncertainties outlined in Chapter 2, and propagated to airborne lidar biomass maps (Chapter 4) is highly desirable. We envision other community-developed tools to be developed and published in the coming years, and to enable transparent validation that leverages such tools, novel approaches to product intercomparison and validation **are recommended**.

One such example is the new ESA NASA Multi Mission Algorithm and Analysis Platform (Albinet et al., 2020). The MAAP is a virtual, open and collaborative environment for the processing, analysis and sharing of data and development and sharing of algorithms. The MAAP will provide a common platform with computing capabilities co-located with data as well as a set of tools and algorithms developed to support this specific field of research. The goal for this platform is to establish a collaboration framework between ESA and NASA to share data, science algorithms and compute resources in order to foster and accelerate scientific research conducted by ESA and NASA EO data users.

This MAAP is a virtual research environment that (i) will provide access to all BIOMASS, NISAR, ICESat-2 and GEDI campaign data in a unified format; (ii) includes software tools that allow to implement and run algorithms in common open programming languages (Python, C, Fortran, R); (iii) makes available resources for processing large volume of data as well as interact with the data; and (iv) provides the tools for algorithm development (Eclipse Che, Jupyter Notebooks) and sharing (GitLab).

Merging the capabilities of the MAAP, or a similarly transparent platform, with both CEOS mission datasets and biomass products and new reference measurements will enable full traceability in validation activities for biomass. Users will be able to reproduce the validation of product generators or other published product intercomparisons, and thus trust the reported uncertainties on products. Further, if the uncertainty statistics do not suit a given application, they can be updated by a product user. This would therefore mobilize the integration of biomass products into the suite of applications outlined in Chapter 6.

## 8.5 Reference Measurement Recommendations summary

The tables below summarizes the CEOS recommendations for new biomass estimation acquisitions with respect to field plots, airborne lidar (ALS), and terrestrial laser scanning (TLS). The table also highlights where these recommendations differ from established protocols.

**Table 8.2 Summary of recommended specifications for new reference data acquisitions**

<p><b>Recommendations for all data collections</b></p> <ul style="list-style-type: none"> <li>• Data should be free and open within at most 1 year after data collection</li> <li>• Data should be acquired in collaboration with long term field plot networks and local partners wherever possible</li> </ul>	
<p><b>Field plot recommendations</b></p> <ul style="list-style-type: none"> <li>• Square plots <ul style="list-style-type: none"> <li>◦ Easier to link to gridded products</li> </ul> </li> <li>• Large plots (minimum 0.25 ha in tropics, ideally 1 ha plots with 25 or 50 m subplots) <ul style="list-style-type: none"> <li>◦ Minimizes edge effects and geolocation uncertainties</li> </ul> </li> <li>• Smaller plots (&lt;0.25 ha) are acceptable outside of tropics provided airborne lidar available</li> <li>• Stem-mapped where possible</li> <li>• Geolocated with high accuracy, and reported uncertainties</li> <li>• Trained botanist should be employed for species identification</li> </ul>	<p><b>Airborne Lidar Recommendations</b></p> <ul style="list-style-type: none"> <li>• Minimum 4 shots /m<sup>2</sup></li> <li>• Preferably acquired same season as field plots</li> <li>• Acquired within 2 years of field data acquisition</li> <li>• Repeated every ~5 years or when disturbance is detected</li> <li>• Covering at least 3 km<sup>2</sup> <ul style="list-style-type: none"> <li>◦ Cover both the plots and local environmental and forest structure gradient</li> <li>◦ Smaller area of coverage acceptable is only UAV lidar available</li> </ul> </li> </ul>
<p><b>Spatial Distribution of Field Plots</b></p> <ul style="list-style-type: none"> <li>• Plots cover environmental gradients under airborne lidar collection that are locally or regionally correlated to biomass (e.g. topographic gradients)</li> <li>• Sufficient number of plots collected to train a lidar model (min approximately 30, depending on complexity of system)</li> </ul>	<p><b>Terrestrial lidar Recommendations</b></p> <ul style="list-style-type: none"> <li>• Data collection in new or existing long-term plots <ul style="list-style-type: none"> <li>◦ Data augments field measurements, does not replace them</li> </ul> </li> <li>• 1 ha plots preferable</li> <li>• Data acquired in a grid pattern</li> <li>• Spacing 10 m in dense forests, 20 m in open areas <ul style="list-style-type: none"> <li>◦ Can be changed to ensure consistent sampling and minimize occlusion</li> </ul> </li> <li>• Instrument must have ability to range tallest trees in 1 ha plots (150 m range)</li> <li>• Repeated ~ every 5 years or when disturbance is detected</li> <li>• Multiple scans need to be coregistered (either through use of targets or with sensor that has automatic coregistration)</li> </ul>

**Table 8.3 CEOS biomass acquisition recommendations compared to existing network field protocols.** Protocols have been rated as “Meets” or “Exceeds” for specifications that satisfy the CEOS recommendation. For specifications that do not match, the difference is noted. If a protocol does not include a specification, the cell has been left blank.

Protocol /Measurement	CEOS Recommendation	ForestGEO	RAINFOR-GEM- AfriTRON	TERN	NEON
<b>Field plots</b>					
Plot shape	Square	Square or rectangle, but large size also minimizes edge effect	Square or rectangle	Meets	Meets
Plot size	1 ha (0.25 ha min. in dense forests)	Exceeds	Meets	Meets	0.16 ha, woody plants not sampled across entire plot
Subplot size	25x25 m	20x20 m	20x20 m	20x20 m	20x20 m, subplots

					not contiguous for aggregation
Stem map	Yes, where possible	Meets	Meets, but coordinates should always be measured precisely, not estimated	Meets	Meets
# of plots	> 10 - 30	Single large plot	Several to 20		Meets
Cover local gradients (topography, biomass range, etc.)	Yes	Meets, but less so than multiple plots across landscape	Usually	Meets	Meets
<b>ALS sampling</b>					
Shot density	4 shots/m <sup>2</sup> min.			Exceeds	Meets
Area	~3x3 km min.			Exceeds	Exceeds
Return interval	~5 years				Exceeds
Time from field acquisition	<2 years				Meets
<b>TLS sampling</b>					
Plot size	1 ha			Meets	
Sampling pattern	Grid			Meets	
Spacing	10 m (dense veg.) 20 m (open veg.)			Meets	
Return interval	~5 years				
Instrument	Range > 150 m			Meets	

# Appendix A Field plot survey guide

The goal of this guide is to provide recommendations for field plot measurements so that they are as useful as possible for validation of aboveground biomass estimates from remote sensing. These guidelines have been synthesized from recommendations in this document, and survey protocols from ForestGEO (Condit, 1998), the National Ecological Observation Network (NEON; Meier, 2014, 2017, 2018; Thorpe et al., 2016), the Amazon Forest Inventory Network (RAINFOR; O. Phillips et al., 2018), and the Terrestrial Ecosystem Research Network (TERN; A. White et al., 2012; Wood et al., n.d.). The guidelines will make general recommendations for plot establishment and data collection, then expand into specific recommendations for different biomes.

## A.1 Plot establishment

The first consideration when establishing a field plot for validation of Earth Observing remote sensing missions is the nature of measurements taken by the mission. The plot size should be determined by resolution of the biomass product. Also, aboveground biomass may be defined as forest biomass, woody biomass, or vegetation biomass by various measurements, and field measurements should reflect this definition.

A plot could be measured only once, but would ideally be established as a long term monitoring site. Either situation can be useful for validation as long as there is a temporal match between the field and remote sensing measurements. Especially in cases where a monitoring site is being established, stakeholder involvement should be considered:

- Local scientific participation
- Long term protection from human disturbance
- Long term institutional support

A sufficient number of plots should be established to train a lidar model for local biomass maps. Depending on the heterogeneity of the region, 10-30 plots are necessary to develop a biomass map.

### A.1.1 Site Selection

The plot location should be determined before going to the field using maps or satellite imagery. An ideal plot location would have biogeography that is representative of the region. Plots should cover gradients sampled by airborne lidar (e.g. topography, biomass range, etc.) Within a plot,

landform and stand features should be as homogeneous as possible. In addition, the plot should be accessible for measurement.

**Table A.1 Features to consider when selecting a plot location. Plot characteristics should be representative of the regional features (left column) while being as homogeneous as possible within the plot (right column).**

Representative of region	Homogeneous within plot
Climate	---
Soil type	Soil type Soil parent material
Vegetation type	Stand structure Floristics
Disturbance regime	Stand structure
---	Topography

After locating a reasonably representative and homogeneous area, the coordinates of the plot should be randomly chosen to avoid any bias towards large trees or aesthetically pleasing locations while in the field. However, the plot should avoid any major anthropogenic features (e.g. roads, fences) and topographic anomalies (e.g. cliffs, extreme slope).

## A.1.2 Plot geometry

After choosing a location, plot geometry (size, shape, and orientation) should also be determined before visiting the field.

### A.1.2.1 Size

- Minimum recommended plot size of 0.25 ha in the tropics
- Ideal plot size is 1 ha with 25 x 25 m subplots
  - Large plots ( $\geq 1$  ha) help reduce mismatches between field and remotely sensed data (Réjou-Méchain et al., 2019)
  - 1 ha plots with 20 x 20 m subplots match the RAINFOR and TERN networks, but 20-m subplots are less useful for matching resolution of current and planned spaceborne biomass campaigns.
- Plots may be as large as 50 ha to match the size of ForestGEO plots

**Figure A.1 Example layout of 1 ha survey plot. GPS should be taken from starred locations.** (adapted from Wood et al., n.d.)

#### A.1.2.2 Shape

- Square plots are recommended to reduce edge effects
  - Less uncertainty about which trees are in or out of plot
- Reduced edge effects improve match with remote sensing data

#### A.1.2.3 Orientation

- N/S orientation preferable when possible
- Alternative orientations are acceptable if stand or topographic features do not allow for a N/S orientation

### A.1.3 Pairing field and remote sensing data

#### A.1.3.1 Geolocation

Proper geolocation is essential for matching field and remote sensing data. Once a plot's location and geometry have been determined, the plot can be set up in the field (see Condit, 1998; Wood et al., n.d. for survey techniques). The latitude and longitude of the plot center and all four corners should be geolocated using a differential GPS. To minimize geolocation errors caused by taking GPS measurements beneath the canopy, no less than 20 GPS acquisitions should be

averaged at each point (Réjou-Méchain et al., 2019), and preferably 300 GPS acquisitions should be averaged at each point.

### A.1.3.2 Timing

The temporal difference between field and remote sensing measurements should be minimized. For plots that are to be measured only once, this means taking field measurements as close as possible to a remote sensing acquisition. For long term monitoring plots, a sampling schedule should be set and adhered to, with field measurements occurring at the same time of year for each census.

Airborne lidar acquisitions **are recommended** to be repeated every 5 years or when a disturbance has been detected. Field measurements should be collected at least as frequently as airborne lidar data, and preferably in the same year as airborne lidar data. Field data acquisitions may be more frequent than lidar acquisitions. Common sampling schedules in established networks are:

- 1 year sampling interval (1 ha-plot, RAINFOR)
- 1-3 year sampling interval (0.16-ha plot, NEON)
- 5 year sampling interval (50-ha plot, ForestGEO)

As plot size increases, the error associated with a temporal mismatch between field and remote sensing data decreases (Réjou-Méchain et al., 2019), but the mismatch should always be as small as possible.

## A.2 Tree measurements

Field plots should be stem-mapped whenever possible. Individual tree measurements are the input for allometric biomass equations for validation of remote sensing data. Understandably, these measurements should be as accurate and unbiased as possible. Within a plot, all stems  $\geq 10$  cm in diameter should be measured. These stems should be mapped by either:

- X and Y coordinates from SW plot corner (RAINFOR)
- Distance and azimuth from designated points within the plot (NEON)

If multiple censuses will be taken, stems should also be tagged with a unique identifier. With each new census, it is also important to include any stems that have newly crossed the 10 cm threshold.

### **A.2.1 Diameter measurements**

The default height for diameter measurement is 1.3 m above the ground (breast height). There are a number of situations where this point of measurement may be altered because of unusual tree shape (see Condit, 1998 for details).

A diameter tape is the preferred tool for measuring diameter, but a Stepped Diameter Gauge may be more precise for irregularly shaped stems. Errors in diameter measurements can be detected through repeated censuses (Réjou-Méchain et al., 2019).

### **A.2.2 Height measurements**

Measuring tree heights within a plot can be used to develop local height-diameter models. Plot-specific height-diameter models reduce error in over- or underestimation of height caused by reliance on regional or global height-diameter.

Errors in height measurements may be reduced by incorporating lidar-derived height metrics. This is especially true if tree height has been measured with a laser rangefinder using the “sine” method, when lidar coverage can be used to quantify the bias in height (Réjou-Méchain et al., 2019).

### **A.2.3 Data recording**

Below are the minimum fields that should be included in field measurements. Sample data sheets can be found at [ForestPlots.net](http://ForestPlots.net).

- Trees
  - Plot ID
  - Subplot ID
  - X and Y coordinates in m
  - Tree ID
  - Family and species
  - Diameter in mm
  - Point of measurement
  - Health status
- Plot
  - Latitude and Longitude
  - Elevation

- Bearing of plot axis

Errors in recording tree measurements can lead to downstream over- or underestimation of biomass. To reduce errors, double entry and proofreading of field measurements is recommended (Réjou-Méchain et al., 2019).

## **A.3 Biome-specific considerations**

### **A.3.1 Tropical forests**

#### **A.3.1.1 Diameter measurements**

In tropical forests, trees with buttress roots and lianas growing against stems are common, and can result in overestimation of diameter measurements. To reduce this bias, a consistent protocol should be followed:

- Lianas: when measuring a tree, diameter tape should be slid underneath lianas
- Buttress roots: the diameter point of measurement (POM) should be 50 cm above the top buttress
  - Carefully record POM
  - If buttress is within 30 cm of POM
    - Measure original POM
    - Establish and measure new POM 50 cm above original POM

Figure A.2 Trees with buttress roots (left) and lianas growing against the stem (right) at Barro Colorado Island, Panama.

### A.3.1.2 Timing

To reduce errors in diameter measurements caused by variations in stem water content, it is best to measure tropical forests during the wet season, when water availability is most consistent.

## **A.3.2 Temperate forests**

### **A.3.2.1 Sampling design**

In temperate forests, plots smaller than 0.25-ha are acceptable, as long as they are accompanied by airborne lidar. As always, matching the remote sensing measurements should be considered when deciding plot size and sampling interval.

- Plot size should match the resolution of the remote sensing product
- Minimum recommended plot size is 10 x 10 m
- High quality geolocation is necessary for small plots
- Temporal proximity to remote sensing acquisition is especially important for small plots

### **A.3.2.2 Plot type**

The use of variable radius plots should be avoided if the prime purpose of the plots is for comparison or cal/val of remote sensing products. This plot type is historically common in temperate forests, but because it does not have defined plot boundaries, it is difficult to pair with remote sensing data.

### **A.3.2.3 Timing**

For consistency between field censuses, diameter measurements should occur after the end of the growing season.

## **A.3.3 Boreal forests**

### **A.3.3.1 Sampling design**

In boreal forests, because of greater homogeneity of stand structure and composition, and slow growth rates, plots can be smaller and sampled less often. Plots smaller than 0.25-ha are acceptable, as long as they are accompanied by airborne lidar. As always, matching the remote sensing measurements should be considered when deciding plot size and sampling interval.

- Plot size should match the resolution of the remote sensing product
- Minimum recommended plot size is 10 x 10 m
- High quality geolocation is necessary for small plots
- Temporal proximity to remote sensing acquisition is especially important for small plots
- In NEON boreal sites, sampling interval is increased from 3 years to 6 years

### **A.3.3.2 Bryophyte sampling**

Bryophytes such as *Sphagnum* spp. form dense mats that significantly impact above ground productivity in boreal systems. Sampling bryophyte biomass should be considered for sites with high bryophyte cover (see Meier, 2014 for sampling design). However, the applicability of bryophyte biomass measurements to validation of remote sensing products will vary (i.e. more applicable to spectral data than lidar)

### **A.3.4 Mangroves**

In mangrove forests, plots smaller than 0.25-ha are acceptable, due to the difficulty of making the measurements (moving and standing water, aboveground root systems, muddy soils). Plots should be co-located with airborne Lidar measurements and the number of plots should be stratified by height classes. Plot size should match the remote sensing measurements and forest structure - with bigger plots for taller trees and smaller plots for denser, shorter forests.

- Minimum recommended plot size is 10 x 10 m
- High quality geolocation is necessary for small plots
- Individuals with DBH < 10 cm should be measured
- Prop and Buttress roots: the diameter point of measurement (POM) should be measured at the point directly above the buttress, for some individuals with prop roots extending well into the canopy, it is not necessary, practical or accurate to measure above the highest prop root
- For shrub and low stature mangroves under 140 cm or total height and stem diameter should be measured

### **A.3.5 Drylands**

Low tree cover and greater dominance of shrubs is often typical in dryland systems. Special considerations for when shrubs make up the majority of the overstory and a plot lacks trees include:

- Individuals with DBH <10 cm should be mapped and measured
- Shrub stem diameter should be measured at the base of the stem instead of breast height. Record POM.
- Cover should be quantified using the point-intercept method along transects in a 20-m grid (see A. White et al., 2012 for details)

The use of variable radius plots should be avoided. This plot type is sometimes used to extend dryland plots with low tree cover, but because it does not have defined plot boundaries, it is difficult to pair with remote sensing data.

## A.4 Accommodating TLS measurements

Ideally, plots should be established to accommodate terrestrial laser scanning (TLS) measurements. Scanning positions are distributed throughout a plot, with each scan generating a point cloud. Neighboring scans are combined to create a scan of the entire plot.

Sampling may also occur in existing long-term plots. A plot size of 1 ha is preferable.

### A.4.1 Sampling pattern

The primary concerns for acquiring TLS data over a large area are to have uniform point density sampled across the whole plot, and sufficient retro-reflective targets to register the location of each scan in relation to others. Dense vegetation blocks TLS sampling, requiring a denser sampling pattern. A sampling pattern should be chosen which yields consistent sampling and minimizes occlusion.

- Dense understory: 10 m scan position grid
- Open understory: 20 m scan position grid
- TLS measurement points and retroreflector targets must continue outside of the plot
- Sample in a chain pattern (Wilkes et al., 2017)
- Time campaigns when forest conditions and climate are consistent
- Instrument must have ability to range to tallest trees (e.g. Riegl vz400 or greater)

**Figure A.3 Example TLS sampling design in a chain pattern.** A 100 x 100 m plot with a 10-m sampling grid. A TLS scan location would be placed at the ends of each arrow.

## A.4.2 Linking to census measurements

For long term monitoring plots, steps should be taken so that repeated tree censuses and TLS measurements can be linked over time.

- Use same local origin, measurement units and reference coordinate system for TLS and field measurements (Wilkes et al., 2017)
- Repeated scanning acquisitions should be <1 m from original location (Wilkes et al., 2017)
- Permanent retroreflector targets at subplot corners for co-registration (Wilkes et al., 2017)

Acquisitions of TLS should be repeated every 5 years or when a disturbance has been detected. Preferably, TLS and field data acquisitions should occur in the same season.

## A.5 Airborne lidar measurements

Ideally, airborne lidar measurements will be acquired in the same season as field plot measurements. Airborne lidar acquisition should occur no more than 2 years (ideally < 1 year) from field data acquisition. Airborne lidar measurements should be repeated approximately every 5 years or following a detected disturbance.

A minimum area of 3 x 3 km should be sampled with airborne lidar. This area should cover all field plots, and any local environmental and forest structure gradients. A smaller sampling area is acceptable when using a drone. A minimum shot density of 4 shots/m<sup>2</sup> (ideally ≥8 shots/m<sup>2</sup>) is required for small footprint discrete return lidar. Large footprint waveform lidar would have value added for many forest structure researchers, but either high to medium resolution waveform lidar (e.g. NASA LVIS), discrete return lidar (e.g. Optech, NASA GLiHT) or many UAV-LS lidar systems provide sufficient accuracy for collection of reference data.

## A.6 Data availability

Ideally, all field validation data should be made open and public to maximize its usefulness across projects. Yet, unlike satellite measurements the actual acquisition of ground data is rarely funded via government space agencies. Field-work requires specific skills and for many field-leaders and PIs the prime motivation may not be Cal-Val, but one or more of a host of other interesting scientific questions - most of which require long-term, multi-site, and painstaking effort to address. It follows that the incentives to make data open and public are maximised if the Earth Observation community actually contributes to the cost (viz, 'he who pays the piper calls the tune'). Calls for 'public' and 'open' data therefore need to be tied to efforts to contribute to the

long-term sustainability of plots, and the valorisation of the scientists and assistants who make measurements.

Once funded and acquired, field data can be contributed to a repository so that the data are well-documented and easy to access for others. There are several available options, including:

- ForestPlots.net
- The Joint ESA-NASA Multi-mission Algorithm and Analysis Platform
- The Forest Observation System (FOS; <https://forest-observation-system.net/>)

## Appendix B Quantifying GNSS geolocation errors

To quantify the error associated with GNSS measurements in a dense forest, we took advantage of a grid laid out by a professional topography consultant using a total station over a 25-ha forest plot located in Gabon, the Rabi CTFS plot (Memiaghe et al., 2016). A terrestrial lidar acquisition (unpublished data) suggested that the position of the grid markers yielded an error between 10 and 30 cm. We took 208 reference points over the materialized plot markers using a high-grade GNSS device (Trimble L1/L2 GEOXT 7000 rover) with the Floodlight technology option activated (to filter out multipath signals). Differential correction was performed through post-processing using base data acquired by a SXBlue L1/L2 GNSS device with full sky view, and located 1.3 km away from the plot center. Post-processing was applied using Trimble Pathfinder Office software. Only code (not phase) signal correction proved possible, as is customary under vegetation. Terrestrial lidar data were acquired over a total of 1.5 ha, using a Leica C10 scan station, with high resolution acquisitions (i.e. 0.05 m between point at 100 m) taken every 10 m along the NE (X axis) direction, and every 20 m along the NW (Y axis) direction. Scans and targets were positioned on plot marker positions, using a closed traverse survey approach (Fig. 2). 2D rigid (translation, rotation) transforms (angle and scale preserving) were estimated from the TLS global coordinate system to the plot grid referencing system (relative X and Y) to the geographic coordinate systems on the basis of the positions of the plot markers in these different systems (Torr & Zisserman, 2000). The reference (best) transform was obtained using all 208 measurements. A sensitivity analysis was then performed by deriving new transforms in a Monte Carlo permutation approach (1000 iterations) by progressively removing points. The accuracy of the new transforms was assessed using the positions estimated using each transformation matrix on the full set of points. X and Y differences were averaged and then converted to Euclidean distance.

**Figure B.1 Sampling setup for assessing the quality of the reference projection.** Green to red height maps illustrate the canopy height model (CHM) derived from terrestrial lidar and grey levels colors depict an airborne lidar CHM (Labrière et al. in press). Black triangles indicate the DGNS positions of measured plot markers. The two panels at the bottom illustrate the co-registration difference between terrestrial and airborne lidar data. Metric reference system (UTM 32S). We acknowledge Drs. Alfonso Alonso, Hervé Memiaghe and David Kenfack for giving access to the Rabi plot and to the data acquired by the professional topography consultant. We also acknowledge S. Momo for giving access to the TLS acquisitions.

## Appendix C Quantifying errors associated with incidence angle, plot size and geolocation

We used a simplistic conceptual sensitivity analysis, using a set of ellipsoid crowns, produced using realistic dendrometric curves and allometric equations, as described in Barbier et al. (2012). We did not account for radiative transfer. For the simulation, representative 200 x 200 m forest stands were generated. To facilitate the numerical analysis, crown ellipsoids were converted to voxels (cubic cells) of 0.5 m sides. We considered that a square field plot with finite limits allows for an exact accounting of the volume of tree crowns within these limits. Similarly, a square remote sensing footprint provides an exact measurement of the intercepted crown volumes down to ground level. We assessed the effect of plot/footprint size (from 20 to 100 m), geolocation precision (from 0 to 30 m) and satellite incidence angle (from 0 to 50°) on total crown volume estimation obtained from the two viewpoints. To obtain a distribution of errors, each combination of the tested parameters was applied on three independently generated forest stands, to which ten different random horizontal rotations were applied. The discrepancy between the crown volume obtained for a given combination of shift, length and tilt and that measured in the field plot can be assessed in two ways. The first one is to only consider the difference in the actual measured volume, allowing for compensations from the surrounding forest. The other measure only considers the proportion of the crown volume initially measured in the plot that is also measured by the RS signal (no-compensation).

# Appendix D List of potential BRM Sites

**Table D.1 List of potential BRM Sites as of 26th August 2020.** This list is regularly being updated and currently includes 141 sites. Note not all of these BRM Sites fulfill all the inclusion criteria listed in Section 8.2.
